Distillation design methods are well established and described in detail in the traditional reference texts (see Kister, 1992). The original methods were formulated in the 1920s and 1930s such as the McCabe–Thiele (1925) and Ponchon–Savarit (1921, 1922) methods for binary mixtures, and the rigorous multicomponent analogues of the Lewis–Matheson (1932) and Thiele–Geddes (1933) procedures. Use of the latter trial-and-error methods emphasized the need for the incorporation of suitable numerical techniques to ensure that the solution (of number of stages) would actually converge, and also to reduce the time spent performing the calculations. Designers later came to rely on short-cut design methods, e.g. Fenske (1932), Underwood (1945, 1946, 1948), Smith–Brinkley (1960), etc., to provide ‘ballpark’ results before embarking upon the detailed rigorous calculations. Easier access to mainframe computers in the 1960s, and desktop machines in the late 1970s meant that the time required to perform the numerical calculations was reduced, and developments then centred on design methods which simplified the problem formulation, e.g. matrix manipulation techniques.

The arrival in the 1980s of general flowsheeting design packages such as HYSIMTM and PRO/IITM (replaced by HYSYSTM and PRO/IITM in the 1990s) shifted the design emphasis away from the develop-

ment of specific design methods to the use of commercially available packages which could provide quick and easy short-cut designs. These developments meant that the designer was liberated from tedious calculation but still required a sound knowledge of distillation principles and the ability to analyse the simulation results in order to avoid serious errors. Many papers have been published in the mid-1990s concerning the limitations of the simulation methods (e.g. *Chemical Engineering Progress* 91(6): 63–75, 1995; *Chemical Engineering Education* 31(1): 46–51, 1997), and the problems that can occur if too great an emphasis is placed upon their use with too little feedback from experienced designers (e.g. *Chemical Engineering Progress* 94(6): 63–77, 1998).

Other design packages are available, the most recent developments being the *Computational Fluid Dynamics* (CFD) modelling software. Such packages may be useful for modelling effects within distillation equipment rather than straightforward applications of the equilibrium stage calculations. CFD is discussed later in this article in relation to possible future developments.

Advances in Column Design

The basic equipment used to achieve a separation has not changed significantly within the last half century. A tray (or packed) column is still used to provide contact area between the liquid and vapour phases in order to achieve mass transfer and hence the desired separation. Tray columns are generally preferred (packed columns are used for particular types of separations, or specific situations) and the equipment consists of tall vertical towers with a large percentage of internal free space. Distillation is also characterized by its thermal design requirements and is an energy-intensive process. Advances in column design have tended to focus on improvements in energy usage and/or improved separation efficiencies. Two examples from the literature are the Hige distillation unit and the integral dual column. The Hige high-performance distillation or extraction unit described by Ramshaw (*The Chemical Engineer* (IChemE) June: 17–21, 1987) attempted to utilize centrifugal fields to improve the separation efficiency and to reduce the column size. The dual distillation columns (see US Patent no. 4 681 661 (1987) and *The Chemical Engineer* (IChemE) December: 21, 1987) consists of two concentric columns (the stripping and rectifying sections) arranged one within the other, the reason being an attempt to better utilize heat effects and also to reduce the column height. Neither of these developments (or numerous others described in the literature) has been widely adopted by industry,

possibly because they do not offer significant cost advantages (or because of the conservative nature of the chemical processing industry).

Column Developments

These have centred mainly on a better understanding of the fluid dynamics within the column and specifically across the trays (the first book on this topic was by Lockett in 1986), and also on improved prediction methods for determining plate and overall column efficiencies. A better knowledge of the interrelation of these two aspects is beginning to emerge from several research groups, e.g. Biddulph and co-workers, and their studies of the relationship between Marangoni surface tension effects and plate efficiencies (*American Institute of Chemical Engineers Journal* 37(8): 1261–1264, 1991). A development since the 1970s is the preference for sieve trays, rather than bubble or valve trays which were prevalent up to that time. The *AIChE Bubble Tray Design Manual* (1958) is still used (with modifications) and quoted, even for the calculation of sieve tray efficiencies for which it was not intended and for which it provides rather poor results. However, this older method has provided a starting point for recent studies which examine the significance of fluid-related variables (such as surface tension) and how this knowledge can be used to design more efficient tray columns.

Many papers have been published in the more industry-orientated journals (e.g. *Chemical Engineering* (NY), *Chemical Engineering Progress* and *Hydrocarbon Processing*) concerning column operation and performance problems. These papers also discuss particular aspects of internal column design and use of the newer structured packings, now available as alternatives to tray systems, in relation to column performance and operation. The use of high efficiency packings requires a better understanding of the hydrodynamic conditions and the mass transfer processes that occur in the packing. Fouling and plugging within distillation equipment can become serious problems and they are areas in need of better understanding. High surface area packings are popular because they promote efficiency, however they are also more prone to fouling problems.

If solids are present in a stream then design solutions generally act to keep the solids moving. Therefore any liquid maldistribution within the column or tray channelling (due to initial vapour maldistribution) must be corrected to avoid plugging problems. Plugging and fouling have varying effects depending upon the actual in-service conditions, and hence it is difficult to devise generic strategies or solutions. General advice tends to focus upon the need for good

distributor design, good wetting (and wettability) of the mass transfer surface, and good distribution of the flow streams within the equipment.

Papers describing column operational problems, such as product draw limitations especially for column revamps (*Chemical Engineering Progress* 94(6), 63–77, 1998), are particularly useful for designers and process operators.

Energy-intensive Nature of Column Design

The energy-intensive nature of column design and operation is unlikely to change significantly, mainly because the requirements for the reboiler to provide vapour flow and the condenser to provide liquid product are essential aspects of the separation. An additional constraint is that the heat removed by the condenser is typically low grade and of little use elsewhere in the plant. Traditional solutions have been to use vacuum operation in the column to lower the boiling point of the mixture (especially for heat-sensitive materials), and to utilize low-grade heat from other plant operations to provide the reboiler duty. Attention has been directed towards lowering the energy requirements of a column, e.g. by reducing the reflux ratio. Energy-saving revamps have replaced trays with packings in order to create more theoretical stages within a column, and hence reduce the reflux rate and boil-up rate. The integration of columns within a sequence and the use of overhead vapours in another column's reboiler (e.g. by use of a Rankine cycle) have also been considered. Energy saving and integration techniques have become standard design procedures since the 1970s (including the use of pinch technology and heat exchanger network design). However, it is difficult to achieve (or to envisage) large scale reductions in the thermal requirements of distillation due to the inherent basis of the separation itself, i.e. latent heat of vaporization is required for the essential partial vaporization at each stage. The most likely developments in this area are the use of hybrid systems, e.g. membranes + distillation, which effect a part of the separation in a less energy-intensive operation (see the section below on developments and applications).

Particular Techniques and Situations

This section considers only two specific aspects of distillation operations, namely process control and difficult separations (e.g. azeotropes).

Chemical Process Control

This was mainly in the hands of electrical/instrument engineers until the mid-1960s, and most of the

published literature reflected their particular expertise. Since that time process control has developed as a significant area of chemical engineering expertise and publication. Many academics have adopted and published in this field (see Luyben, 1992) and there are also several handbooks and practical texts dealing with plant operations (e.g. Shinskey, 1984). Distillation was one of the primary chemical engineering unit operations to be researched and developed in depth for process control applications. This was because of the scope offered by distillation as a control problem and the range of options and alternatives available. The focus of distillation control is usually the product specification, but the critical operations of reboiler and condenser performance, the uncertainty of feed-point location, the reflux rate, and the need for correct internal functioning (e.g. fluid flow on and between the trays) means that several complex relationships and problems need to be considered together. The number of publications dealing specifically with distillation control attests to the complex nature of the problem and the number of approaches and applications that are possible within any single situation. An additional consideration for the designer is the possible number of column arrangements, utilizing several columns, and their possible alternative specifications (hence the advantages offered by simulation packages), and therefore the integration of individual column control within the overall control of a set of distillation operations.

Developments in distillation control have focused on several areas, generally searching for optimal solutions to the following:

1. Individual column control (including reflux streams, and reboiler and condenser operation and performance).
2. Control of a column required to perform a specific separation (e.g. heat-sensitive mixtures) or a particular type of application (e.g. separation of azeotropes or close-boiling mixtures; reactive distillation).
3. Control of sequences and arrangements of several columns.

Distillation control has developed into a multifaceted problem incorporating mass transfer and separations, process modelling and optimization techniques, instrumentation and control functions, and the application of simulation packages in order to evaluate a range of possible problem solutions. Control theory has now developed to include a range of advanced techniques such as adaptive control, model-based control, and the use of neural networks which supplement the basic approaches offered by combina-

tions of proportional, integral and derivative (P-I-D) control functions.

Difficult Separations

Difficult separations using distillation techniques depend primarily upon the nature and properties of the components in the mixture, rather than the physical arrangement of the equipment such as bubble caps versus sieve trays, tray versus packed columns, etc. Reactive distillation is an exception to this generalization (see next section). Distillation contrasts with other separation techniques such as membranes and adsorbents where the characteristics of the actual separation media have a significant effect upon the ability to separate the components. This is why generic distillation methods have been developed and used effectively whereas there is no single theory or method available for the design of either membrane or adsorption systems. However, distillation was developed in order to separate mixtures of components exhibiting significant differences in relative volatilities and boiling points and problems arise where this is not the case. In particular, azeotropes exhibit no difference in volatility (at certain conditions) and hence no change in the composition of the mixture obtained. Traditional approaches have been either to avoid the conditions where an azeotrope forms, or (more likely) the addition of a solvent or entrainer which 'breaks' the azeotrope but which also requires an additional column(s) to remove and recycle the solvent. The common azeotropes are well known and documented, e.g. ethanol/water, acetone/chloroform, etc. Recent developments have centred on the ability to predict the occurrence of an azeotropic mixture (or a mixture with very little difference in component volatilities), and also on the application of the traditional design methods to the design of a range of column configurations. These configurations aim to produce an optimum separation in terms of product specification, minimum use and recycle of solvent, effective and feasible control schemes, minimum capital and operating costs. Computer-based property packages have been developed specifically to predict azeotrope formation, and the vapour-liquid equilibria data can then be used in an appropriate column simulation package to evaluate the alternative equipment arrangements. Researchers have developed prediction and property packages by the application of basic thermodynamic principles, and also utilizing specific equations of state (see section on VLE data above). The property packages have also included data on available solvents. The aim is generally to combine azeotrope prediction with solvent selection, and full specification of the combined mixture properties for use in column design simulations.

Developments and Applications

Reactive or Catalytic Distillation

Reactive or catalytic distillation has emerged as a significant development in recent years, the original patents were obtained by L.A. Smith in the early 1980s. Several research groups have considered a range of specific systems and applications and a substantial body of literature has been published. The main system that has been investigated and reported is the production of methyl *tert*-butyl ether (MTBE) mainly due to the high efficiency of the process, and also the related systems of ethyl *tert*-butyl ether (ETBE) and *tert*-amyl methyl ether (TAME). The technique includes reactive (homogeneous catalyst) or catalytic effects (heterogeneous catalyst acts as the packing) within the traditional distillation equipment. The design requires a combination of the well-known mass and energy balance equations with the individual reaction mechanisms, and consideration of heats of reactions. The design of such systems requires modelling of the mass transfer, reaction and separation, thermal effects, and the inherent control systems. An additional requirement is the knowledge of any possible side reactions and by-product formation, and their effect on the final separation of the mixture produced.

If a catalyst is required then the physical installation of this material, its removal and replacement, and its effect upon the fluid dynamics within the column become important additional operational and design considerations. The distillation column now becomes a countercurrent two-phase flow, fixed-bed reactor. Packed beds typically have a void fraction of 0.7 (even up to 0.95), whereas small catalyst particles result in a voidage of 0.3–0.4 which makes countercurrent operation impractical. Therefore catalyst support structures must be designed and incorporated to provide a voidage of at least 0.5, and in addition allow for expansion and contraction of the bed, and provide a uniform catalyst spatial distribution. An alternative is to manufacture the catalyst in the shape of a distillation packing. For certain systems there are distinct advantages from employing reactive distillation, but their dynamics are complex and careful consideration of the operation and control are required in order to avoid potential difficulties.

Hybrid Separation Systems

Hybrid separation systems combining two or more unit operations have become popular in the 1990s, and there are numerous examples in the journal literature. Many of the examples have combined distillation with a membrane-type technique, thus aiming to

utilize the well-known data and methods (and separation efficiency) of distillation with the low temperature advantages offered by membrane systems. Osmotic distillation (or isothermal membrane distillation) has been developed specifically for applications requiring the retention of flavours and fragrances (*Chemical Engineering Progress* 94(7): 49–61, 1998). This hybrid process can concentrate solutes to very high levels at low temperatures and pressures, and it is particularly suitable for sensitive solute materials. It can also effect the selective removal of a single volatile solute from an aqueous solution. The process involves the transfer of volatile components between two inherently miscible liquid streams, separated by a semipermeable membrane, the driving force being provided by differences in component activity between the streams. The strip solution becomes diluted during separation/transfer and must be reconcentrated by distillation (or evaporation). Many other examples of membrane–distillation systems can be found in the literature. Alternative hybrid systems include crystallization–distillation, solvent extraction–distillation, pervaporation–distillation, and fluidized reaction–distillation. These systems have been described in some detail including patents, although generally the work is directed towards a particular application or problem.

The Future: Developments and Applications

Future developments would seem to be most closely linked to the areas already outlined in this chapter rather than sudden and unexpected applications. Distillation is a mature separation technology and developments are likely to be in incremental advances in our knowledge and understanding of the process itself, and in the underlying principles that determine its ultimate effectiveness for separating components.

The most likely areas for significant advances and developments are:

1. Further combinations of mass transfer effects within distillation equipment (tray or packed columns), developing the current trends of reaction with distillation (reactive and/or catalytic distillation), and hybrid systems of membranes (or other techniques) with distillation.
2. Improvements in separation effectiveness (and costs) including attempts to reduce the size of the equipment, increased efficiencies, and reductions in energy requirements.
3. More reliable prediction and modelling techniques directed towards VLE predictions, efficiency models and predictions, and improvements in the CAD

modelling packages in order to identify practical limitations of the simulations at an early stage.

4. Development of separation systems incorporating distillation in order to address specific environmental problems and applications.

Significant applications are expected in the use of *computational fluid dynamics (CFD) packages* for prediction of effects occurring within distillation equipment. This is a different area of research from the use of the flowsheeting packages and the calculation of equilibrium stages. The CFD approach (generally using commercial packages such as PHOENIXTM and FLUENTTM) has been used to predict single-phase flow patterns (of a vapour phase) from numerical solutions of the Navier–Stokes equation, turbulence equations, and the continuity equation. If the equations of momentum and mass transfer are inserted into the CFD methodology then it may be possible to predict the flow patterns and their effects upon tray performance. However, the major challenge is the consideration and modelling of the three-dimensional froth height and its shape.

Reviews of the state-of-the-art in distillation and the need for and possible directions of future research have been discussed by Fair (1988), Kunesh *et al.* (1995) and Porter (1995). Assessments of advances and developments in distillation equipment regularly appear in the journal literature, e.g. *Chemical Engineering* (NY), December 1992; *Hydrocarbon Processing*, February 1989; *The Chemical Engineer* (IChemE), September 1987. Fouling and plugging in equipment and a better understanding of the internal flow mechanisms and regimes are areas receiving and requiring further attention, as discussed earlier. Most new ideas tend eventually to become either an academic curiosity, or niche applications, and approximately every 10 years a new technique gains attention and prominence, e.g. reactive distillation, membrane-distillation.

Introduction

Distillation columns have been widely used in the past to separate mixtures of liquids into individual components. And even though new separation techniques are being developed, distillation remains the

most important separation method applied in the process industries today.

The layout of a simple distillation column is shown in **Figure 1**. A single feed enters the column at the side and two products are produced: the light or most volatile components are withdrawn from the top and heavy components are removed from the bottom. Heat (in the case shown, steam) for evaporation of the liquid is supplied to the reboiler, and heat is removed (in this case, through cooling water) at the top in the condenser. The nomenclature used in this

Figure 1 Distillation column layout.

chapter is shown in **Figure 1**, where V = vapour flow, F = feed flow, R = reflux flow, D = distillate flow, B = bottom flow, x = composition, M = mass hold-up and W and S are cooling water and steam flow respectively. In order to maintain constant separation in the distillation column, it should be well instrumented and controlled. The treatment of instrumentation and control techniques will focus primarily on packed columns or columns with trays.

A number of excellent books and review articles have been written about distillation control. Shinskey's book (1984) is a very practical one and provides a good introduction to the subject of distillation control, although a detailed explanation of different approaches to control alternatives is always clear to the novice. The book by Buckley *et al.* (1985) provides a comprehensive treatment of pressure, level and protective controls; control of composition is restricted to a short treatment of composition dynamics in binary columns. The book edited by Luyben (1992) is probably the best starting point: It has been written by several experts in the field of distillation dynamics, instrumentation and control. It provides a comprehensive treatment of distillation models, distillation simulation, identification of distillation processes and selection and comparison of control structures. In addition, several chapters are devoted to

particular case studies. The *Process Control Instrument Engineers' Handbook* (Liptak, 1995) also provides three interesting sections on distillation control: one section discusses basic controls, another section discusses advanced controls and in a subsequent section the subject of relative gain calculations is reviewed. The handbook also provides a wealth of information on instrumentation.

A book which gives a good introduction to batch distillation control is the one by Fisher (1990) and Luyben (1992) gives a good overview. Three review articles should be mentioned as a starting point for further reading; the first one is by Tolliver and Waggoner (1980: 195 references), another is written by McAvoy and Yang (1986: 270 references), and the one by Skogestad (1992) also provides easy-to-understand material: it has 206 references.

Because vapour and liquid with a certain energy content are present in the column, basic instrumentation includes measurements of the vapour hold-up (column pressure), liquid hold-ups (column bottom level and reflux drum level) and generally a number of temperatures along the column. In addition, the in- and outgoing flows are usually measured, as shown in **Figure 1**.

Since the feed to the distillation column is often fixed by a preceding process, no control valve is

shown in this flow, although sometimes the feed pre-heater control valve is used to control the amount of feed that vaporizes. This means that five manipulable flows remain and there are essentially five degrees of freedom for control. However, the vapour and liquid hold-ups have to be controlled, which means that $5 - 3 = 2$ degrees of freedom remain, which are generally used for composition control.

Distillation columns pose some interesting control problems. First of all, the process is often highly nonlinear. Secondly, there are five variables to be controlled (pressure, P , level, h_B , level, h_R , composition, x_D , composition, x_B) and five variables which can be manipulated (flows R , D , B , S and W). How the coupling between these controlled and manipulated variables should be established has been an interesting field of study for many years. In our approach a matrix (Figure 2) is constructed where all variables are listed; for each combination of controlled output and manipulated input the control quality is determined. The control quality can be established on the basis of speed of control, power of control and the requirement of minimal interaction between control loops. The speed of control is related to the period of oscillation of the control loop at the limit of stability. The shorter this period, the higher the speed of control. The power of control relates to the range over which control is effective. For an acceptable combination, the speed of control should be large, as

should the power of control – in other words, the controlled output should respond quickly to changes in the manipulated process input. However, there are not always five variables to be controlled. It could be that there is no strict requirement for the column pressure, in which case it is often optimal to minimize the pressure and open the cooling water valve of the condenser completely. It could also be that there is a strict requirement for the top product composition but no requirement for the bottom composition, in which case there would be an extra degree of freedom.

The issue of column operation, column instrumentation and selection of the right pairing between controlled process outputs and manipulated inputs will be considered in more detail in the following sections.

Objectives for the Separation Process

The main objective of the distillation process is usually the recovery of a valuable component from the feed. In that case there is also often a quality requirement for this valuable component. If the purity of the valuable component is low, then the product has little value. If the concentration meets the specification, then the product value is high.

There may be no distinct quality requirement, in which case the economic value of the product could be a continuous function of the product properties.

Let us assume that both top and bottom product represent an economic value. Then an economic objective for the operation of the process could be defined as:

$$J = c_D D + c_B B - c_F F - c_S S \quad [1]$$

where c_D is the top product value (\$ kg⁻¹), c_B the bottom product value (\$ kg⁻¹), c_F the cost of the feed (\$ kg⁻¹) and c_S the cost of the steam (\$ kg⁻¹). The use of cooling water usually involves little cost and fixed costs do not play a role in the optimization of the operation.

If F is fixed and the overall material balance $F = B + D$ is substituted in eqn [1], then the variable part J_d of eqn [1] can be written as:

$$J_d = D - \frac{c_S}{c_D - c_S} S \quad [2]$$

Figure 3 shows both terms as a function of the steam flow to the column reboiler. When S increases, the yield of the valuable product approaches asymptotically a value which is equal to the amount of top product which is present in the feed: $D_{\lim} = F X_{F,lk} / X_{D,lk}$, where the subscript lk refers to the light key component.

	Basic control

W					
B					
D					
R					
S					

Figure 2 Control matrix, showing controlled and manipulated variables.

Figure 3 Optimal steam usage in distillation process.

The maximum value of J_d is found when the tangent to the curve for D parallels the straight line for $c_s S / (c_D - c_B)$, as shown in **Figure 3**. The optimum point may be located within the operation area. But at different values of the feed, however, some constraint may make the optimum point unreachable, in which case the optimum lies on the constraint.

Control of Vapour Inventory

There are a number of ways to control the vapour inventory or column pressure. Even though one of the five flows indicated in **Figure 2** could be used for pressure control, only the use of W and S gives sufficient power of control. If S were used for pressure control, a step increase in S would result (via higher pressure and top temperature) in an increase in the vapour flow in the top. Consequently, the concentration of the less volatile components in the top would increase, resulting a higher top temperature and consequently a higher vapour flow in the top. This positive feedback can sometimes be so strong that the pressure finally attains a lower value (inverse response). Therefore, the most common method of pressure control is through manipulation of the coolant flow, W .

If a water-cooled condenser is used, the water flow rate is manipulated to control pressure: if an air-cooled condenser is used, the fan speed is generally changed. The attractiveness of this pressure control option is that the condensed liquid is at its bubble point and is not subcooled, as may be the case with other pressure control options.

If there are incondensable gases in the system, pressure could also be controlled through manipulation of a bleed valve, through which the gases are bled from the column. The bleed valve is often installed on top of the reflux drum.

It should be emphasized that the pressure has a large degree of self-regulation. If the pressure in a column increases, the temperature will also increase

and because of this the heat transfer in the condenser will increase; consequently the pressure will decrease again to a certain extent.

The general recommendation for pressure control is:

1. if the condenser performs partial condensation, control the column pressure by manipulating the vapour flow leaving the column;
2. if there is no net vapour flow from the column, the next preferred option is to control pressure by manipulating condenser duty, e.g. by changing the coolant flow.

Control of Liquid Inventory

Liquid inventory of the distillation process can be controlled by controlling the liquid levels: the base level in the column, h_B , and the level in the reflux drum, h_R . Often the levels serve the purpose of smoothing disturbances, hence for control of the reflux drum level the combination (h_R, D) or (h_R, R) is suitable, since W is already used for pressure control and B and S provide insufficient power of control.

For bottom-level control, D is unsuitable since the power of control is nil. Hence both (h_B, S) and (h_B, B) are suitable combinations, since they both have a large power of control.

Under normal circumstances the most logical combinations are to use the distillate flow for controlling the reflux drum level and the bottom flow for controlling the column base level.

In columns with a small distillate flow, D , and a large reflux flow, R , this scheme does not work so well. This problem can be partly eliminated by establishing a ratio controller between distillate and reflux flow. When the distillate is then increased, the ratio controller will increase the reflux flow accordingly. However, in many cases with a small distillate flow, the reflux is used for reflux drum-level control. A similar situation holds for the bottom of the column. If the bottom draw-off B is very small, level control using the liquid draw-off might not work well. In that case one could use the steam flow for base-level control. However, increasing the steam flow to the reboiler (and accompanying larger vapour flow in the column) might temporarily increase the bottom level in the column. In the long term, however, increased heat input will result in increased evaporation and consequently a lower bottom level (**Figure 4**). This response is called inverse response or nonminimum phase response and is not desirable for control purposes.

For tray columns this effect can easily be quantified using detailed column models. Assuming that any increase in vapour flow will propagate through the

Figure 4 Bottom-level response to a positive change in steam flow.

column relatively rapidly, linearizing liquid dynamics and using deviation variables, the liquid flow from tray 1 can be written as (Figure 5):

$$\delta L_i = \lambda \delta V + \frac{1}{\tau_L} \delta M_i \quad [3]$$

in which:

$$\lambda = \left(\frac{\partial L}{\partial V} \right)_{M_i}, \quad \tau_L = \left(\frac{\partial M}{\partial L} \right)_V \quad [4]$$

where τ_L is the tray hydraulic time constant. Neighbouring trays will have similar parameter values, hence the term $\lambda \delta V$ is the same everywhere, and therefore initially all changes in liquid flows will remain the same. The mass balance on each tray will

Figure 5 Schematic of a stage of a distillation column.

therefore initially remain at equilibrium, resulting in no change of liquid content on the trays. However, for the top tray, N , where the same flow of liquid (reflux) is still entering, a mass balance combined with eqn [4] gives:

$$\delta M_N = \frac{\tau_L \lambda \delta V}{1 + s \tau_L} \quad [5]$$

Substituting eqn [5] into eqn [3] and writing the result for the entire column yields for the liquid flow change for the bottom tray:

$$\delta L_1 = \lambda [1 - G_d(s)] \delta V \quad [6]$$

with:

$$G_d(s) = \frac{1}{(1 + \tau_L s)^N} \quad [7]$$

For the column bottom level it can then be written that:

$$\delta h_B = \frac{K_B}{s} \{ \lambda [1 - G_d(s)] - 1 \} \delta V \quad [8]$$

where K_B is the gain of the bottom level in response to vapour flow changes.

From eqn [8] it can be seen that an inverse response can exist, as long as λ is not equal to zero. The magnitude of the inverse response depends on the magnitude of λ . For some columns negative values of λ have been found; for others λ is positive. It can be shown that bottom-level control on the steam (vapour flow) is strongly delayed by the effect of λ when $\lambda > 0.5$. The physical interpretation of the so-called λ -effect is that with large tray loads, an increase in vapour flow will lead to stagnation of the liquid flow and consequently λ will be larger than 1. With small tray loads an increase in vapour flow will push more liquid off the tray, thus a larger liquid flow to the lower bottom will result. Figure 6 summarizes all options for control.

Quality Control

The response of the key components to variations in liquid and vapour flow can be approximated by the algebraic sum of the relative flow variations followed by a first-order response with a large time constant:

$$\delta x_i = \left(\frac{\delta L_{i+1}}{L_{i+1}} - \frac{\delta V_{i-1}}{V_{i-1}} \right) \frac{K_x}{1 + \tau_x s} \quad [9]$$

	Basic control				
	P	h_B	h_R	x_D	x_B
W	++		+	+	+ unless $\hat{\lambda} > 0.5$
B		++ unless $V_B/B \gg 1$			
D			++ unless $R/D \gg 1$	+	
R			+	++	
S	+	+ unless $\hat{\lambda} > 0.5$		+	++ unless $\hat{\lambda} > 0.5$

Figure 6 Possibilities for the control scheme.

where L and V are the liquid and vapour flow respectively (see Figure 5), K_x is the gain for concentration responses and τ_x is a large time constant for concentration responses, usually in the order of hours. This time constant is approximately proportional to the square of the number of trays.

For control of the bottom quality, the reflux R or distillate flow D are unsuitable candidates, since there is a large dead time in the dynamic response between the flow and the composition. The steam flow S and coolant flow W are acceptable candidates for bottom quality control, unless, for the same reason as holds for bottom-level control, the parameter:

$$\hat{\lambda} = \frac{V_i}{L_i} \left(\frac{\partial L}{\partial V} \right)_{M_i} \quad [10]$$

is larger than 0.5. The bottom flow B does not have a direct impact on the bottom quality; it could have some impact via a level controller.

For top quality, R , W and S are all suitable candidates for control. If, however, pressure is controlled by manipulating coolant W , the only viable option for bottom composition control is the steam flow S , after which the only remaining option for control of the top quality is the reflux R . Not in all cases, however, is there a dual composition requirement, which leaves more options for composition control.

Location of Sensors

It is important to provide the column with adequate sensors: flow measurements and pressure measurements at various locations, for example above the top tray, at the feed tray and below the bottom tray in order to be able to calculate pressure differentials for the purpose of detecting flooding. Temperature sensors should also be positioned at various locations along the column. In many cases temperatures can be used to infer composition. When the temperature difference between top and bottom of the column is small, inferring composition from temperature measurements is generally not feasible, even though in some cases temperature differences may still provide a reasonable composition estimate. An advantage of using temperature differences is that it is insensitive to pressure changes; unfortunately, the correlation between temperature difference and product composition is often highly nonlinear. In multicomponent mixtures, the relation of tray temperature to key component composition is not unique. Furthermore, the tray temperature to key product composition may also be nonlinear. Therefore, care must be taken in using temperatures for controlling composition. For high purity distillation columns sometimes the logarithm of the temperature (or composition) is used to linearize the response of the distillation column.

When the temperature difference between column top and bottom is large, several temperatures should be measured at trays above and below the feed tray, where under normal circumstances the temperature break is located. These temperatures should then be averaged and could be used in manipulating, for example, the steam flow.

An excellent treatment of sensor and valve issues in distillation control is given by Luyben (see Further Reading); the location of temperature sensors receives an especially comprehensive treatment.

For a distillation column first the base control scheme should be established, i.e. pressure, reflux drum level and column bottoms level should be controlled. Then two variables remain available for control of composition, say the reflux R and steam flow S .

If temperature is used for control of composition, the problem of proper temperature sensor location becomes prime importance.

If only one composition is controlled, a simple procedure could be followed. By giving a small change in the reflux R , the sensitivity $\delta T_i / \delta R$ can be determined for each tray. A similar procedure can be followed for the steam flow S . A typical plot for a toluene-*o*-xylene column with 30 trays is shown in Figure 7. It can be seen that a 1% change in steam

Figure 7 Gain matrix graph for the toluene-*o*-xylene column.

flow causes a temperature change of about 10° at tray 24. A 1% change in the reflux flow causes a maximum temperature change on tray 26 of about -4° . Therefore the sensitivity of the temperature to changes in steam flow is larger than the sensitivity for changes in reflux flow. Where there is dual composition control, sensor sensitivity should be balanced against sensor interaction. One tool that has been used to accomplish this is singular value decomposition. The sensitivity matrix X , which contains the sensitivity of the temperature on each tray for changes in reflux and steam and thus contains two columns and 30 rows, is now decomposed into three individual matrices:

$$[U, S, V] = \text{SVD}(X) = USV^T \quad [11]$$

Luyben gives a comprehensive treatment of the use of the individual matrices and their physical meaning and suggests computing a new function (combination of the principal components) for each tray:

$$Z_i = |U_{1,i}| - |U_{2,i}| \quad [12]$$

The maximum of Z_i is an indication for the best location of the first sensor, while the minimum of Z_i gives the best location for placement of the second sensor. For the toluene-*o*-xylene column this was calculated and the results are shown in Figure 8. The

Figure 8 Sensor placement based on U-vectors.

best location for the first temperature sensor is tray 25, and the best location for the second sensor is tray 28. Note that the location has changed somewhat compared to the best locations for the single composition control problem (trays 24 and 26). This is a result of the process of reducing the interaction between the vector components at the other trays.

In many columns temperature has been used to control the separation process. For binary systems at constant pressure there is a unique relationship between temperature and composition. For multicomponent mixtures, often a simple relationship may be found between temperature and composition. If the column pressure is not controlled tightly, temperature measurement should compensate for pressure variations:

$$T_{\text{compensated}} = T_{\text{measured}} + S(P_{\text{reference}} - P_{\text{measured}}) \quad [13]$$

where S is the inverse of the slope of the vapour pressure-temperature curve at normal operating conditions.

No matter how attractive it is to control temperature rather than composition, the ultimate objective of the separation process is to control composition(s). This means that an analyser should be used to indicate the true compositions. There are, however, a number of disadvantages using analysers in control. First of all, analysers are highly sophisticated instruments and are therefore expensive and require extensive maintenance. In addition, the sampling system of analysers is prone to malfunctioning and as analysers are often used for multiple streams the response can exhibit a large dead time. This means that simple feedback control using analysers often results in poor control performance and dead time compensation techniques often have to be used to improve performance.

Analysers are well suited for use in a cascade control set-up, where the temperature (or combination of temperatures) controls one of the flows and the analyser controller resets the temperature controller setpoint. Figure 9 shows one possibility, using the reflux as manipulated variable.

Control Configurations

From Figure 6 it is clear that controlling the top composition by the reflux (R) and the bottom composition by the vapour flow V (or steam flow S) is just one possible option. This control option is called the RV configuration or energy balance structure and it is probably one of the more frequently used options for dual composition control in many distillation columns. In the literature other options for controlling

Figure 9 Composition control in a cascade structure.

both top and bottom composition are discussed and compared, such as the *DV* configuration and *RB* configuration, which are called the material balance structures.

Use of Feedforward and Decouplers

In many cases the top and bottom composition control loops will show interaction and it is advisable to

design and implement decouplers. Depending on the required purity of the products and on the selected control configuration, decoupling is sometimes difficult to achieve. However, for many industrial distillation columns, decoupling considerably improves the performance of the composition control loops Figure 10.

The main source of disturbances usually enters the column with the feed. Whereas the feed composition may vary somewhat, the feed flow varies considerably in many cases. In those situations it might be worthwhile applying feedforward control. If the reflux is controlling the top composition and the steam flow the bottom composition, then feedforward affects both these flows on a column feed change. The principle for the reflux controller is shown in Figure 11, which shows a feedforward controller for feed flow changes. In a similar manner, a feedforward controller for feed composition changes could be implemented. Reflux affects the tray temperature, say via a model G_R . If the feed affects the tray temperature via a model G_F , then the feedforward controller has the structure G_F/G_R . One word of caution is necessary: care should be taken to identify properly both models, since a poorly designed feedforward controller may cause poorer control performance than no feedforward controller at all.

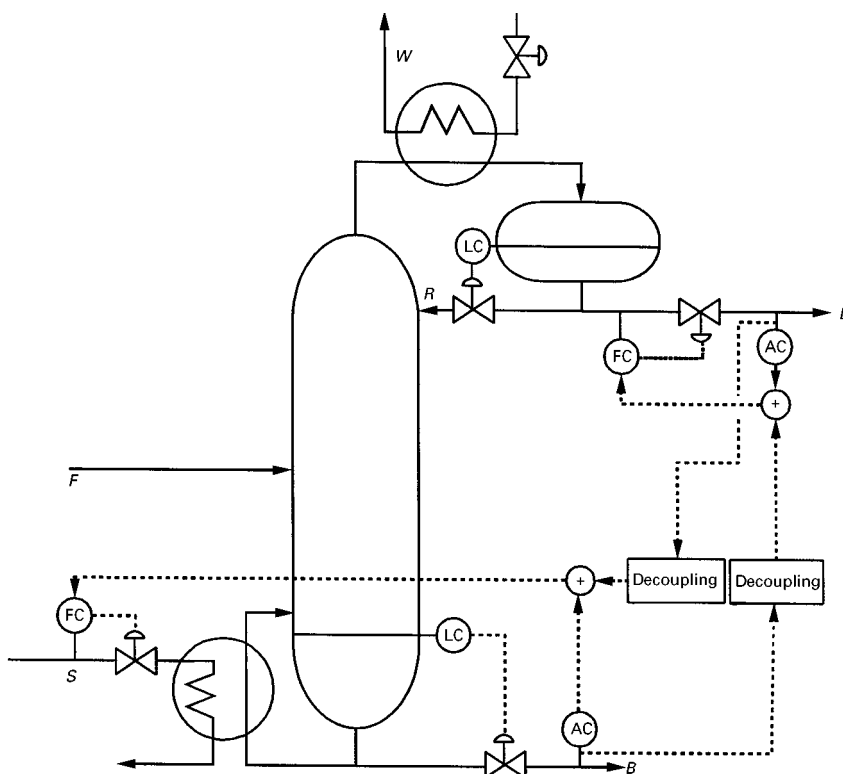

Figure 10 Example of dual analyser control using *DV* configuration with decoupling.

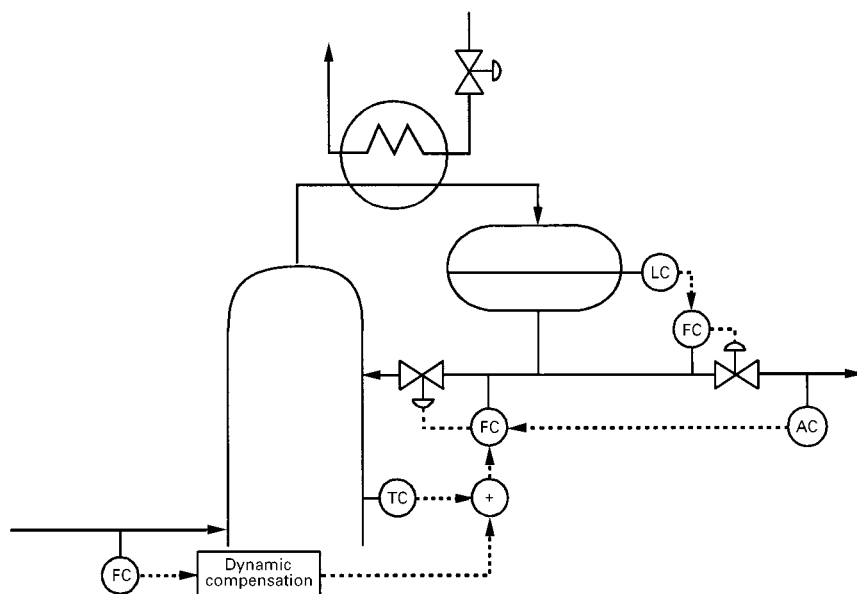

Figure 11 Principle of feedforward control.

Ratio Control

From eqn [9] it follows that keeping L/V constant will reduce variations in the concentration. Figure 12 shows this ratio control implemented. Usually one cannot directly measure the vapour flow V , but a reasonable estimate can be made in many ways, for example from a static heat balance over the condenser:

$$V_{\text{top}} = F_{\text{water}} c_{\text{water}} (T_{\text{water,in}} - T_{\text{water,out}}) / \Delta H_c \quad [14]$$

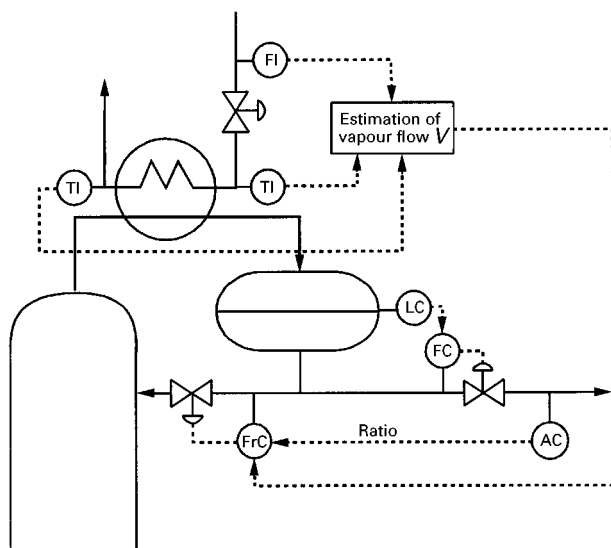

Figure 12 Ratio control between vapour flow and reflux flow.

in which ΔH_c is the heat of condensation and c_{water} is the specific heat of water.

Although this estimate of the vapour flow is not dynamically correct, the quality controller can be tuned such that the control scheme works well.

Multivariable Control

It is possible to consider the 5×5 control problem as an integrated problem for which an integrated controller should be designed. One technique which tries to accomplish this is multivariable predictive control. In this design all the input–output relationships of the process are identified by means of proper plant testing. Based on the models, a controller is designed, which adjusts all five process inputs simultaneously utilizing all measured process outputs. In its unconstrained version the controller is:

$$\Delta u = (A\Gamma A^T + \Gamma_m)^{-1} A^T \Gamma e \quad [15]$$

in which Δu is a vector with the changes in process inputs, A is a matrix with step weight coefficients which represent the model dynamics, Γ is a diagonal matrix with weights representing the relative importance of the process outputs, Γ_m is a diagonal matrix with penalties for the process input changes and e is a vector of process output error predictions into the future.

Model predictive control works well for distillation columns; it becomes more attractive for larger systems, such as heat-integrated distillation columns.

One of the major benefits of model predictive control is its capability in handling constraints. In that case the control problem is usually solved using quadratic programming or some other optimization technique. Commercial software packages are available for model identification and controller implementation.

Conclusion

Instrumentation and sensor location has been discussed for a distillation column. In addition, a comprehensive treatment is given of the various options for control. It is shown that some understanding of column dynamics is necessary in order to select the proper control schemes.

Laboratory Scale Distillation

R. C. Gillman, Riverside Organics Inc., Lincoln Park, MI, USA

Copyright © 2000 Academic Press

Distillation on a scale ranging from research quantities as small as ten milligrams to multikilogram lots is commonly encountered in the laboratory. Based upon the physical and chemical properties of the substance to be isolated, in addition to those of the attendant impurities and the quantity of impure product to be distilled, a technique can often be chosen which will result in a product of adequate purity in one operation. It may be said that planning a synthesis should include consideration of the difficulty one may encounter in separation of the mixture of products resulting therefrom; on the bench several alternate routes to the desired product may be available, and the resultant mixtures will differ in ease of separation. Since the quantities are not large, more expensive reagents may be chosen, if desirable, than would be acceptable in a manufacturing process. A major saving in time and effort can often be thus effected.

Resort is commonly had to three broad classes of distillation, steam distillation, flash or simple distillation, and fractional distillation. The first, finding use in separation of substances volatile with steam from those which are not steam-volatile, often uses the basic equipment of simple distillation described below, with steam being sparged into the distilland; either the product is collected as part of the condensate of the residual distilland is enriched in the desired product by removal of steam-volatile impurities. This technique, when applicable can be a powerful and convenient method requiring less skill and attention than fractional distillation.

Simple, or flash, distillation is in general used to separate individual compounds from mixtures consisting of substances whose boiling points differ by at least 40°C, and mixtures of volatile and nonvolatile components. The method consists of simply boiling the mixture in a vessel equipped with a device, commonly referred to as a 'head' which conducts the vapour to a condenser wherefrom the resultant liquid is collected. The head is usually equipped with a means by which the vapour temperature may be

observed. No forced reflux is used in this method of rectification; all the vapour reaching the head is condensed as efflux. In order to minimize entrainment of droplets, some form of dephlegmator can be interposed between the pot and the head. This technique can be conducted at pressures ranging from atmospheric to the lowest pressure available; pressures as low as 0.01 torr are not unusual. Very small quantities of product can be distilled using a device known as a 'kugelrohr (ball-tube) apparatus'; it is constructed of two or more spherical globes connected linearly by glass tubing to each other and to a vacuum source. The globe most remote from the vacuum source is charged with the distilland and vacuum is applied; the unit is rotated by hand in a horizontal position while the globe containing the distilland is heated by flame or oil bath. The vapour condenses in the globe nearer the vacuum source.

It must be stated that the development of preparative gas chromatography, a powerful and convenient method, has in most cases obviated the necessity of distillation of quantities less than 25 g. Separations hardly realizable with the most sophisticated and cumbersome techniques can be accomplished in minutes using this method; the fractions taken are usually of a high degree of purity as isolated.

The remaining method, fractional distillation, is normally used to purify quantities of crude product larger than approximately 100 g, although apparatus such as the Podbielniak column, constructed of a metal helix fitted snugly into a small-diameter glass column, have been utilized successfully to fractionate amounts less than a tenth as large. The separation efficiency of such a column can be very high but throughput is very low. As stated, preparative gas chromatography is currently the method of choice for small quantities. For rectification of larger quantities a variety of apparatus is available, and the choice of equipment rests upon the predicted difficulty of the separation to be accomplished. As mentioned, on the bench one may be able to choose a synthetic scheme which results in an easily purified crude product; when this is not feasible recourse is had to a more efficient system capable of separating components whose boiling points lie close together.

As a rule of thumb, if the components of a mixture differ in boiling point by at least 30°, satisfactory partition can be achieved by use of Vigreux column, which is constructed of a glass tube 16–25 mm in diameter 20 cm to 1 m in length having tiers of indentations spaced 1.5–2 cm apart. The fractionating efficiency of the Vigreux column is quite good considering the ease and economy of construction of the unit.

Due to its relative openness the throughput of such a column is quite high, and as a result this type of

column has become the workhorse in many preparative laboratories; its efficiency may be further enhanced by operating it under forced reflux. Throughput of 0.1–1.5 L h⁻¹ are common when using this column. An additional advantage to use of this column is the ease of repair; most repairs can be made in the laboratory.

In cases where the boiling point differentials between component is less than 30°C, use of a more efficient column to effect partition will usually be found advantageous. These units are of three basic types; the first in which contact between liquid and vapour in the column is forced by mechanical construction of the column, the second in which the structured packing is used to present a large surface area to promote vapour-liquid interaction in the column (such as a bubble-cap column), and the third, a column filled with glass or metal objects of various geometries such as metal saddles, glass beads, and glass helices. The last type is often referred to as 'dumped packing'.

Units of the first type, whereby the vapour and liquid are forced into contact by the construction of the column are fairly efficient and can be designed for a reasonably high throughput. They are, however, very expensive and quite fragile when constructed of glass; thus, while they have found major application in industrial processes, where the construction is only of metal, in the laboratory they have not found use to the extent to which packed columns are used. Repairs to glass columns of this type are difficult and expensive.

The second type, structured column packings, are usually made up of a fairly closely woven metal mesh, which is then crimped and rolled into cylindrical sections which are pushed into a glass or metal column; the packed length of such a column typically will be 0.6–3.0 m for laboratory use, with diameters of 25–100 mm. The packing itself can be fabricated from many different metals, for instance stainless steels, monel, or tantalum depending on the chemical nature of the product to be purified. The advantages of this type of column are relatively high throughput, low pressure drop and moderate to high fractionation efficiency. They can be designed to operate at pressures as low as 0.1 mmHg and even greater than atmospheric pressure. In practice, however, the high vapour velocities and low vapour densities encountered at pressures less than 1 mmHg result in significant degradation of column efficiency, especially if a moderate throughput is required. As to size, a column of this type whose internal diameter is about 25 mm would be suitable for use with a distillation pot of 5 L capacity, while for use on a 50 L pot a column of 75–100 mm internal diameter would

suffice. In addition, this type of column is quite easily constructed, easily repaired if broken, and can be used to predict the performance of an industrial unit of similar construction. In the laboratory, throughput of $0.1\text{--}2.0\text{ L h}^{-1}$, depending on pressure, can be expected.

The last group of columns, the so-called 'dump packed' type, are as a group the most efficient at fractionation and can be the most tedious to use. They can be filled with a variety of packings, from Raschig rings (short sections of glass tubing) to columns packed with single turn glass helices dropped individually into the column. The latter is one of the most efficient fractionating columns ever devised, but as will be seen, is more suitable for distillation of smaller batches. In practice, columns of this design intended for laboratory use are $0.6\text{--}2.5\text{ m}$ in length, with internal diameters of $15\text{--}60\text{ mm}$. Packing fabricated of perforated metal should be purchased after consultation with the manufacturer; a nominal size of $0.4\text{--}1.0\text{ cm}$ is usually chosen for bench use. Of the various packing components, a column filled with glass helices of $4.5\text{--}8.0\text{ mm}$ diameter has proven to have the greatest efficiency per unit column length but this advantage is offset to some extent by the low throughput and high pressure drops attendant with use of these units. Raschig rings are cut to a length approximating their external diameter from glass tubing $6\text{--}12\text{ mm}$ in size. Columns filled with dumped packing have one advantage other than efficiency in that they can easily be emptied and refilled with some other type of packing should such be desirable; conversely, structured packing, once installed can be difficult if not impossible to remove from the column without out ruining it. The disadvantages of dumped packings are a tendency to form channels through which vapour can pass without contacting liquid, low throughput, and, in most cases, high pressure drop, in addition to being prone to flooding. As a result these columns are seldom used at pressures below 10 mmHg ; fractionation efficiency and throughput suffer markedly at lower pressures. In spite of these disadvantages columns of this construction have found use in many laboratories because of their ability to successfully perform separations not possible with columns of other design. Throughputs of $0.025\text{--}0.5\text{ L h}^{-1}$ can be expected from these columns.

General Comments

The efficiency of any distillation column is dependent to some extent upon its being operated under adiabatic conditions. Thus, distillation columns are usually insulated, enclosed within a silvered vacuum jacket, or enclosed within a heated jacket the temper-

ature of which can be measured and controlled to within about 3°C of the vapour in the column. Too much heat will result in superheating of the vapour, causing insufficient condensation and reboiling as the vapours proceed up the column; too little heat can result in excessive condensation and flooding in the column.

Since maximum efficiency also depends upon operation at or near thermal equilibrium it is important to be able to change from one fraction to another without interrupting the distillation. A number of designs are available from scientific laboratory glass supply houses to accomplish this. In this connection, it will be found convenient to install some form of manostatic device in the vacuum line to prevent pressure fluctuations during the course of the distillation.

The source of heat input to the pot must be provided with various zones such that the heat input to the flask may be restricted to the area of the flask immersed in the distilland as the distillation proceeds. Failure to control the heat input in this way will result in serious superheating of the vapour as the distillation nears its end; driving superheated vapour into the column will result in significant loss of efficiency.

Finally, allusion was made to use of forced reflux during fractionation; it is exceedingly important to the maintenance of column equilibrium and thus fractionation efficiency. Even with a simple column such as the Vigreux, use of a partial takeoff head will result in increased ability of the system to furnish fractions of relatively high purity. In the case of packed columns control of reflux is absolutely essential to proper column performance; in its absence vapour-liquid equilibrium is never established resulting in loss of up to 90% of the fractionating efficiency of the column. Typically, reflux ratios (reflux ratio is defined as the ratio of the amount of condensate returned to the column to the amount of condensate collected as efflux) as high as 50:1 are not uncommon during difficult separations; ratios approaching 1:3 are sometimes used during centre cuts or end fractions. Various means to effect reflux control are available from laboratory glass suppliers, from simple devices utilizing manual control by means of a stop-cock to elaborate units in which a magnetically controlled valve is used to divert the condensate stream either to the column or to the receiver.

Caution

Since a difficult fractionation may consume days, during which the pot is at constant reflux, heed must be paid to considerations of thermal stability in the distilland, especially since small quantities of acids or bases can, and do accelerate thermal degradation of

some organic chemicals. In fact, some thermal decompositions have been shown to be autocatalytic. It therefore may be well to consider flash distillation of the crude product prior to subjecting it to fractional distillation to remove trace non-volatiles and/or non-volatiles which would accelerate decomposition or lead to excessively high pot temperatures. In some cases one might consider the addition of a stabilizing agent to the pot to retard decomposition.

Closing Remarks

With all of the above having been stated, fractional distillation, particularly at reduced pressure, can be viewed as an opportunity to see physical chemistry at work. When selecting a system one hopes will result in satisfactory partition of components it will be

helpful to consider properties other than the boiling point. For example, if a mixture of intermolecularly bound substances is to be separated by distillation, their partition is likely to be more difficult than the differentials between their boiling points would indicate. On the other hand, a mixture of alkanes may well be more easily separable than comparison of their boiling points would otherwise indicate. In any case practice is necessary, both conducting distillations and selecting systems for distillation. Once experience has been gained it is satisfying to be able to rationalize the results of a fractionation in terms of physico-chemical principles. One positive note: since distillation does not result in loss of product, in the worst case one can recombine all the fractions and redistill using different conditions and, if necessary, a different system.

Modelling and Simulation

J. R. Haas, UOP LLC, Des Plaines, Illinois, USA

Copyright © 2000 Academic Press

Introduction

Rigorous computer modelling of all types of fractionation columns has become a necessary part of the development and design process. There are numerous software products available to do these calculations. An understanding of the basic mathematics used in these programmes is helpful to select, use and troubleshoot a column model. Explained here are the basic equations, numerical and solution methods commonly used.

Stage and Column Models

A rigorous method describes a column as a group of equations and is the mathematical engine to solve and satisfy these equations to calculate the operating conditions of the column.

Column design and performance calculations present the column at steady state, that is, what enters the column matches what leaves it (material and energy balances), i.e.:

$$\begin{aligned} \sum (\text{molar feed flow rates}) \\ = \sum (\text{molar product flow rates}) \end{aligned}$$

$$\begin{aligned} \sum (\text{mass feed flow rates}) \\ = \sum (\text{mass product flow rates}) \end{aligned}$$

$$\begin{aligned} \sum (\text{moles of any component in the feeds}) \\ = \sum (\text{moles of the component in the products}) \end{aligned}$$

$$\text{Feed enthalpy} + \text{Heat added}$$

$$= \text{Product enthalpy} + \text{Heat removed}$$

Figure 1 shows a complex column with one feed and one side product. The top stage of the column is a partial condenser, with a vapour product, D , and a liquid product, d . The reflux is the liquid, L_0 , and the reflux ratio is $L_0/(D + d)$. The bottoms product, B , leaves stage $N + 1$, the reboiler. The stages are numbered from the top, with the condenser as stage 0, the top tray in the column, stage 1, the bottom tray, stage N , and the reboiler, as stage $N + 1$.

An ideal or equilibrium stage is where vapour and liquid entering and leaving the stage are perfectly mixed and there are no inhibitions to material transfer between the phases. The material and energy flows in and out of a simple stage, with no feeds or side products, is stage j depicted in Figure 2, and i represents the component number. Components are numbered from 1 to the last, C .

The enthalpy terms, H_i and h_i , are molar enthalpies of the vapour and liquid leaving the stage, respectively. These molar enthalpies are multiplied by the total flow rates, V_i and L_i , leaving the stage to give the total energy leaving the stage in each phase.

The feed stage model (stage f in Figure 2) for an equilibrium stage assumes that the feed liquid mixes

Figure 1 Overall column model with external variables.

with the liquid entering the feed stage while feed vapour mixes with vapour leaving the stage (though special consideration is made for the vapour feed at the bottom of absorber/stripper columns). The distribution is found by an adiabatic flash of the feed at the

feed stage pressure before the feed enters the column. Regardless of whether the feed is subcooled liquid or superheated vapour, or if true mixing occurs, the assumption of an equilibrium stage is maintained in most rigorous methods.

Figure 2 Model of stage variables.

Similar models are drawn for the bottom and top stages of any column, plus other equipment such as product withdrawal stages (stage p of Figure 2), pump-around returns and draws, and inter-reboilers and inter-condensers. Since a reflux, reboiler vapour, feeds, or returns are often subcooled, superheated, or very different in composition from the material on the stage, the assumption of an equilibrium stage rapidly becomes invalid.

Equations of Distillation Modelling

The basic equations below fully describe a distillation column. These equations define the overall column total material balances, energy balances, and product compositions. Internal to the column, they describe equilibrium conditions, internal (stage-to-stage) component and total material balances, and internal energy balances. The independent variables of a column are the product rates and compositions, internal vapour and liquid rates and compositions, and stage temperatures. Equilibrium constants, also called K values, and mixture enthalpies are dependent vari-

ables. Each stage is assumed to be at equilibrium (a theoretical stage), though an efficiency can be applied in the equations.

The equations were first referred to as the MESH equations by Wang and Henke (1966). The MESH acronym stands for:

- Material or flow rate balance equations, both component and total.
- Equilibrium equations including the bubble and dew point equations.
- Summation or Stoichiometric equations or composition constraints.
- Heat or enthalpy or energy balance equations.

The MESH variables are referred to as state variables. These are:

- Stage temperatures, T_j
- Internal total vapour and liquid rates, V_j and L_j
- Stage compositions, y_{ji} and x_{ji} , or instead, component vapour and liquid rates, v_{ji} and l_{ji}

The equilibrium equation is:

$$y_{ji} = K_{ji}x_{ji} \quad \text{or} \quad v_{ji}/V_j = K_{ji}l_{ji}/L_j$$

The equilibrium constant or K -value, K_{ji} , can be a complex function itself, dependent on the compositions, x_{ji} and y_{ji}

$$K_{ji} = K_{ji}(T_j, P_j, x_{ji}, y_{ji})$$

The dependence of K_{ji} on x_{ji} and y_{ji} often appears in the MESH equations. The component rates can also be expressed in the terms of each other, giving:

$$v_{ji} = l_{ji}(K_{ji}V_j/L_j) = l_{ji}S_{ji}$$

and

$$l_{ji} = v_{ji}(L_j/K_{ji}V_j) = v_{ji}A_{ji}$$

$K_{ji}V_j/L_j$ is termed the stripping factor, S_{ji} , while $L_j/K_{ji}V_j$ is termed the absorption factor, A_{ji} .

The summation equation or composition constraints simply states that the sum of the mole fractions on each stage is equal to unity. For the liquid phase:

$$\sum_{i=1}^C x_{ji} - 1 = 0 \quad \text{or} \quad \sum_{i=1}^C l_{ji}/L_j - 1 = 0 \quad \text{or} \quad \sum_{i=1}^C y_{ji}/K_{ji} - 1 = 0$$

and for the vapour phase:

$$\sum_{i=1}^C y_{ji} - 1 = 0 \quad \text{or} \quad \sum_{i=1}^C v_{ji}/V_j - 1 = 0 \quad \text{or} \quad \sum_{i=1}^C K_{ji}x_{ji} - 1 = 0$$

For a simple column (single feed, no side products), the overall component balance equation is:

$$f_i - d_i - b_i = 0$$

The component balance for the simple stage (no feed or side product), j , of Figure 2, is:

$$v_{j+1} + l_{j-1} - v_{ji} - l_{ji} = 0$$

The component balance for feed stage, f , of Figure 2 will add the liquid portion of the feed, l_{Fi} , while the vapour portion, v_{Fi} , is added to the component balance for stage $f-1$. For the product stage, p , the

material withdrawn, w_{pi} , is subtracted from the component material balance. By convention, material leaving a tray has a negative value and material entering a tray has a positive value.

The total material balances are organized in the same manner as the component balances. The total material balance for the simple stage of Figure 2 is:

$$V_{j+1} + L_{j-1} - V_j - L_j = 0$$

The same convention applies to feed and product trays where the total flow rate of a feed, F_j , is positive and the product, W_{ps} , is negative.

The equilibrium equation and the composition constraint are combined to get the bubble point equation:

$$\frac{1}{\sum_{i=1}^C l_{ji}} * \sum_{i=1}^C K_{ji}l_{ji} - 1 = 0$$

and the dew point equation:

$$\frac{1}{\sum_{i=1}^C v_{ji}} * \sum_{i=1}^C \frac{v_{ji}}{K_{ji}} - 1 = 0$$

These, or some variation, are important in some methods to find the stage temperature, especially for more narrow boiling mixtures.

The energy balance equations are required in any rigorous method. In narrow-boiling mixtures, they influence the internal total flow rates. In wide-boiling mixtures and in columns where there are great heat effects (e.g. oil refinery fractionators) they also strongly influence stage temperatures. The overall energy balance for a column with one feed and side product is:

$$FH_F - DH_D - Bh_B - WH_W + Q_R - Q_C = 0$$

The enthalpy terms, H and h , are per mole of mixture. Note that the enthalpies of the top and side products are written so that a vapour or liquid enthalpy can be substituted, depending on the phase of the product. The energy balance for the simple stage, j , of Figure 2 is:

$$v_{j+1}H_{j+1} + L_{j-1}h_{j-1} - V_jH_j - L_jh_j = 0$$

The enthalpies (energy per mole) for each phase are functions of temperature, pressure and composition:

$$H_j = H_j(T_j, P_j, y_{ji})$$

$$h_j = h_j(T_j, P_j, x_{ji})$$

For feed stages, side product stages, and stages with inter-condensers or inter-reboilers, additional terms are included in the energy balance equations. The energy balance for the reboiler is:

$$L_N h_N - V_{N+1} H_{N+1} - B h_{N+1} + Q_R = 0$$

and for a partial condenser with both vapour and liquid products:

$$V_1 H_1 - L_0 h_0 - d h_0 - D H_0 - Q_C = 0$$

Subcooling is accounted for in h_0 (the enthalpy of the reflux, L_0 , and the liquid distillate, d).

Most computer simulations work with ideal stages but to characterize a stage for the deviation from ideality or equilibrium, stage efficiencies are often used in some software. Commonly, a Murphree vapour efficiency is used for each component, given as:

$$E_{MVji} = \frac{y_{ji} - y_{ji-1}}{y_{ji}^* - y_{ji-1}}$$

where y_{ji}^* is what the vapour composition would be if the vapour were in equilibrium with the actual liquid on the stage and y_{ji} and y_{ji-1} are actual vapour compositions. If the absorption factor is used, the vapour efficiency can be expressed in terms of variables already presented:

$$E_{MVji} = \frac{v_{ji} - v_{ji+1}(V_j/V_{j+1})}{(K_{ji} V_j/L_j)l_{ji} - v_{ji+1}(V_j/V_{j+1})}$$

A vaporization efficiency, E_{ji} , based on the Murphree efficiency is defined as:

$$E_{ji} = E_{MVji} + (1 - E_{MVji}) \frac{y_{ji+1}}{K_{ji} x_{ji}}$$

This can be used in the MESH equations to account for stage nonideality. This vaporization efficiency is applied to the equilibrium constant, K_{ji} , and appears as the product $E_{ji} K_{ji}$. The vaporization efficiency does solve a computational problem in placing an efficiency in the MESH equations. A major disadvantage of the vaporization efficiency is that it does vary with composition. Near the top of a high purity column, as y_{ji+1} and x_{ji} approach unity, E_{ji} also approaches unity, and so a vaporization efficiency does not truly reflect stage nonidealities.

Another efficiency method is the bypass method where some of the vapour flow of a component entering the stage is sent to the next stage to account for its

inefficiency in separation. The bypass method cannot be used on trays that have material leaving or entering from outside the column such as a feed tray, product draw tray, pump-around return or draw tray, or side-stripper return or draw tray. The bypass method will cause one of these trays to be out of mass balance. Some of the trays adjacent to these trays are also affected by these actions. In some columns, this eliminates a large number of trays and makes results difficult to apply.

Caution then should be used in any choice of efficiency. More often, it is usually best to perform the rigorous calculation using ideal stages and then apply an overall column efficiency based on sound engineering judgement and experience to account for stage nonideality, and calculate the number of actual trays or packing height.

Rigorous Computational Methods

Classification of the Methods

The rigorous methods can be divided into four basic classes. These are:

- The bubble point methods (BP)
- The sum-rates methods (SR)
- The 2N Newton methods
- The global Newton or simultaneous correction (SC) methods.

The BP methods get their name because the stage temperatures are found by directly solving the bubble point equation. The BP methods generally work best for narrow-boiling, ideal or nearly ideal systems; where composition has a greater effect on temperature than the latent heat of vaporization.

The sum-rates (SR) method is suitable for modelling absorbers and strippers with extremely wide-boiling systems, especially those with non-condensables. In these columns, temperatures are the dominant variables and are found by a solution of the stage energy balances. Compositions do not have as great an influence in calculating the temperatures as do heat effects or latent heats of vaporization.

The 2N Newton methods calculate temperatures and total flow rates together but compositions are still calculated in a separate, dependent step. The name 2N Newton means that there are two equations per stage for a total of $2 \times N$ functions and variables per column solved simultaneously by a Newton-Raphson method. The 2N Newton methods have been shown to work well for wide-boiling mixtures including refinery fractionators, absorber-stripper columns and reboiled absorbers.

The first three classes are referred to as equation tearing or decoupling methods because the MESH equations are divided and grouped or partitioned and paired with MESH variables to be solved in a series of steps. The SC methods attempt to solve all of the MESH equations and variables together. Additional classes are:

- Inside-out methods
- Relaxation methods
- Homotopy–continuation methods
- Nonequilibrium models.

The relaxation, inside-out and homotopy–continuation methods are extensions of whole or part of the first four methods in order to expand the range of columns, and to solve difficult systems or columns. The nonequilibrium models are rate-based or transport phenomena-based methods that do away altogether with the ideal stage concept and eliminate any use of efficiencies. They are best suited for columns where a theoretical stage is difficult to define and efficiencies are difficult to predict or apply by any means.

Numerical Methods – The Newton–Raphson Technique

The MESH equations form a large system of inter-related, nonlinear, algebraic equations. The mathematical method used to solve all or part of these equations as a group is the Newton–Raphson method. An understanding of the numerical method is needed to understand the performance of all column methods. Detailed discussion of the Newton–Raphson method and its variations can be found in Holland's (1981) text.

The Newton–Raphson is an approximation technique. It assumes in the derivatives that the MESH equations are linear over short distances and the slopes will point towards the answers. The MESH equations can be far from linear and the predictions can take the next trial well off the curves, and move away from the solution. In some rigorous methods based on Newton–Raphson, a poor set of starting values can cause the calculation never to approach a solution. Also, the calculation can oscillate, with values swinging to either side of the solution. The independent variables calculated in a trial need to move the column to a solution. The software should include means to prevent or detect these problems and improve stability, e.g. by damping or limiting the change to the next set of variables. A Newton–Raphson method will normally take even steps toward the solution.

Global Newton Methods

One group of methods that is very popular is the global Newton methods, also called the simultaneous correction (SC) methods. A common one is that of Naphtali and Sandholm (1971), but there are numerous applications in the literature and global Newton methods have been extended to include additional equations and variables for solving three-phase and reactive distillation columns.

In the global Newton methods, all of the equations are solved together in a Newton–Raphson technique. The methods vary in their choice of variables and MESH equations for the Newton–Raphson calculation but none of the MESH equations are solved in any separate step. In the BP, SR and 2N Newton methods, the component balances and compositions lag the other MESH calculations (since K values and enthalpies are generated using the compositions from the previous trial) and compositions of each component are calculated independently of the others MESH variables. These are major disadvantages with highly nonideal systems, where K values (especially activity coefficients γ_{ji}) and enthalpies are highly composition dependent and where the composition of one component cannot be readily decoupled from those of others. The global Newton method includes the component balances among the Newton–Raphson independent functions and compositions join other MESH variables as independent variables.

The global Newton methods are the most sensitive of the rigorous methods to the quality of the initial values and often require initial values near the answer. This, and applying the methods to a full range of column equipment and specifications, is their greatest problem. Variations on global Newton methods are used in the inside-out, relaxation, homotopy and nonequilibrium methods, where their power and reliability is extended.

Inside-out Methods

The inside-out algorithm has become one of the most popular methods because of its robustness and its ability to be applied to the solution of a wide variety of columns. The inside-out concept was developed by Boston (1980). Russell (1983) presented an inside-out method that works well for many refinery fractionators. The inside-out methods are now the methods of choice for mainstream column simulation and have displaced other methods.

In older methods, the MESH variables of temperatures, total flow rates and component flow rates are the primary solution variables and are used to generate the K values and enthalpies from complex correlations. These methods update the MESH variables in

an outer loop with the K values and enthalpies updated whenever the MESH variables change. The inside-out concept reverses this by using the complex K value and enthalpy correlations to generate parameters for simple K value and enthalpy models. These parameters are unique for each stage and become the variables for the outside loop. The inside loop consists of the MESH equations and is a variation on other methods. In every step through the outside loop, the simple models are updated using MESH variables from the inside loop. This sets up the next pass through the inside loop. Since the K values and enthalpies are simple, the inside loop works well for a wide range of mixtures and is little affected by the nonideality of mixtures or the quality of the initial values.

The outer loop K value model is based on a simple composition-independent K method:

$$\ln K_{bj} = A_j + B_j(1/T_j - 1/T^*)$$

where T^* is a reference temperature for the K value correlation. Outer loop variables, A_j and B_j , are generated for each stage from a reference $K_{bj\text{Ref}}$ of a composite component:

$$\ln K_{bj\text{Ref}} = \sum_{i=1}^C w_i \ln K_{ji(\text{actual})}$$

where the w_i are weight factors. The temperatures and compositions used to get the $K_{ji(\text{actual})}$ are the latest from the inside loop. Simple relative volatilities are among the outside loop variables, and are used in the K_b method to calculate the temperatures and whenever K values are needed in the inside loop:

$$\alpha_{ji} = K_{ji(\text{actual})}/K_{bj\text{Ref}}$$

These simple relative volatilities change little over the range of temperatures that is seen on a given stage and greatly simplify temperature and composition calculations in the inside loop. For nonideal mixtures, an activity coefficient for each component accounts for composition effects in the inside loop. This activity coefficient has a simple model, similar to the K_b model:

$$\ln \gamma_{ji}^* = a_{ji} + b_{ji}x_{ji}$$

where the new outer loop variables, a_{ji} and b_{ji} , for each component are determined from the actual activity coefficient model at the current stage temperature and stage composition.

The simple K values used in the inside loop are easily determined from:

$$K_{ji(\text{simple})} = K_{bj}\alpha_{ji}\gamma_{ji}^*$$

Simple models for the enthalpy of a phase are also used to reduce effects such as that caused by components moving past their critical conditions. Thus, the outside loop calculation consists of updating the terms of the simple K value, activity and enthalpy models which are updated after each inside loop solution using the latest temperatures and compositions from the inside loop.

The inside loop consists of the actual calculation of the MESH variables using the simple K value and enthalpy models. Boston initially used an inside loop solution method similar to a bubble point method and from that it may appear that the Boston method is most appropriate for narrow-boiling mixtures. However, the forcing style of the method also allows it to work well for wide-boiling mixtures. The Boston method works well for tall, high purity (superfractionator) type columns, but has been extended to absorbers, to three-phase distillation, and to reactive distillation by using other arrangements of the MESH equations.

The Boston method includes a middle loop to allow for column specifications and constraints. The arrangement of equations in the inner loop, where the solution of the MESH variables occur, may allow for only a few control or specified variables, such as fixed reflux ratio and product rates. The middle loop adjusts the control variables to meet the specifications. The middle loop can be built as an optimization method with process specification equations and economic objectives and constraints.

Russell's (1983) method differs from Boston's in the inside loop by a solution method of the MESH equations that includes specifications for product quality, stage temperatures, internal flow rates, etc., without the use of a middle loop to solve these. Here, for each heat exchanger in the column, plus each additional side product, an additional specification and operating variable is added to the problem. Russell's method has been found to work well for refinery fractionators with side strippers and other similar columns.

Relaxation Methods

A relaxation method finds a steady-state solution of a column as if it were an operating column changing with time. The column is initialized using some realistic condition and then makes steps to the steady-state conditions by successive approximations of the

unsteady-state distillation equations. These unsteady-state equations are modifications to the MESH equations to include changes in the MESH variables with respect to time. This mimics the physical start-up of the column, but the objective is not to follow the dynamic operation but to seek the steady-state solution.

Homotopy–Continuation Methods

Homotopy or continuation methods are applied to difficult-to-solve columns, and are a simple means of forcing a solution. The MESH equations can be difficult to solve, due either to the nature of the column (many feeds or side products, side strippers, near minimum reflux, etc.) or to the nonidealities of the K values or enthalpies. For three-phase systems, azeotropic systems or systems of columns with two or more feed/recycle stream combinations, there may be more than one calculated solution. The method must be forced to reach the desired solution. Homotopy methods begin with a known solution of the column and from there follow a path to the desired solution. The known solution can be at different conditions or with much simpler K value and enthalpy methods and stepped changes are made from there, solving the column equations at each step, until the final solution is reached.

Nonequilibrium or Rate-based Methods

Stage efficiency prediction and scale-up from ideal or equilibrium stages to the actual design can be difficult and unreliable for many columns. For highly nonideal, polar and reactive systems, such as amine absorbers and strippers, prediction and use of efficiencies is particularly difficult. In such mixtures, mass transfer and not equilibrium often limits the separation.

Nonequilibrium methods attempt to get around the difficulty of predicting efficiencies by replacing the equilibrium stage concept. Instead, they apply a transport phenomena approach for predicting mass transfer rates. Here, the bulk vapour and liquid phases are not at equilibrium with each other, but there is equilibrium at the interface between phases with a movement from the bulk phase through the interface (Figure 3). The net loss or gain of material and energy at the interface is expressed as transfer rates. The mass and energy transfer rates are dependent on the mass and energy transfer coefficients for each phase which are in turn dependent on composition and conditions of each bulk phase and at the interface.

The correlations for the mass and heat transfer coefficients and interface also take into account packing or tray geometries for the actual column. The total mass and energy rates are calculated from integrating the mass and energy fluxes across the total interface surface.

Krishnamurthy and Taylor (1986) present and test a nonequilibrium model which includes rate equations among the traditional MESH equations. These include individual mass and energy balances in the vapour and the liquid and across the interface. An equilibrium equation exists for the interface only. The solution methods for these equations are the same as the global Newton methods.

The total mass transfer rates are added to an expanded set of the MESH equations called the MERQ equations. The new MERQ acronym stands for:

Material balances for each component – one for the bulk vapour, one for the bulk liquid and one across the interface.

Energy balance equations – one for the bulk vapour, one for the bulk liquid and one across the interface.

Rate equations for mass transfer for all but one component – one from the interface to the bulk vapour and one from the bulk liquid to the interface, plus one energy transfer rate equation from the liquid to the vapour.

Equilibrium equation at the interface only.

Outlook

New rigorous methods for fractionation modelling may no longer be forthcoming and most enhancements will be driven by greater acceptance of nonequilibrium methods, and to other methods by their application to more complex fractionators and difficult systems of components. Teaching concepts of equations and solution may be limited to what is necessary to understand a programme's options, diagnostics and why a programme acts in a certain manner. There should be greater emphasis on knowledge of the physical reality of a column and where the actual process is sensitive, to help set up a problem. Software improvements are needed more in analysis and troubleshooting thought processes, tools and reports. Some of these tools may be a return to use of pre-computer tools such as x - y , McCabe–Thiele, and Hengstebeck diagrams and shortcut methods. While computers continue to become more common, faster and easier to use, they should never be a substitute for sound engineering experience and judgement.

Multicomponent Distillation

Introduction

Distillation is the oldest separation process and the most widely used unit operation in industry. It involves the separation of a mixture based on the difference in the boiling point (or volatility) of its components. The reason for the wide acceptance of distillation is that, from both kinetic and thermodynamic points of view, distillation offers advantages over other existing processes for the separation of fluid mixtures:

1. Distillation has the potential for high mass transfer rates because, in general, in distillation there are no inert materials or solids present.
2. The thermodynamic efficiency for distillation is higher than the efficiency of most other available processes in the chemical industry.

Designing a distillation column involves: (1) selecting the type of column, mostly based on heuristics; (2) obtaining the vapour–liquid equilibrium data using thermodynamics; and (3) finding the design variables such as number of equilibrium stages and operating conditions required to obtain the desired separation based on mass and energy balances.

When the mixture to be separated contains two components, the design of a column can be accomplished by using *graphical methods*. However, for multicomponent systems the design methods are more difficult and are the focus of this article.

Fundamentals

Simple Distillation

Distillation began as a simple still. In such an operation, a liquid mixture is heated (see Figure 1). As a result, a vapour stream richer in the more volatile components comes off, while the liquid, richer in the less volatile components, remains in the still. The vapour stream is condensed and collected in the condenser.

The analysis of simple distillation for a binary mixture presented in 1902 by Lord Rayleigh marks the earliest theoretical work on distillation. Consider Figure 1. Let F (moles) be the initial feed to the

still and x_F (mole fraction) be the composition of component A of the mixture. Let B be the number of moles of material remaining in the still, x_B the mole fraction of component A in the still, x_D the mole fraction of component A in the vapour dB produced during an infinitesimal time interval dt . The differential material balance for component A can be written as:

$$\ln \left(\frac{B}{F} \right) = \int_{x_F}^{x_B} \frac{dx_B}{x_D - x_B} \quad [1]$$

Complex mass and heat transfer processes occur in distillation processes and it is generally assumed that the vapour formed is in thermodynamic equilibrium with the liquid. Hence, the vapour composition (x_D) is related to the liquid composition (x_B) by an equilibrium relation of the functional form $x_D = f(x_B)$. Note that, because of the unsteady nature of simple distillation, the equilibrium relationship between x_D and x_B holds only for each infinitesimal time interval dt .

The exact equilibrium relationship for a particular mixture may be obtained from a thermodynamic analysis and is also dependent upon temperature and pressure.

Thermodynamics and Equilibrium Data

Accurate and reliable thermodynamic data for vapour–liquid equilibrium is essential to distillation

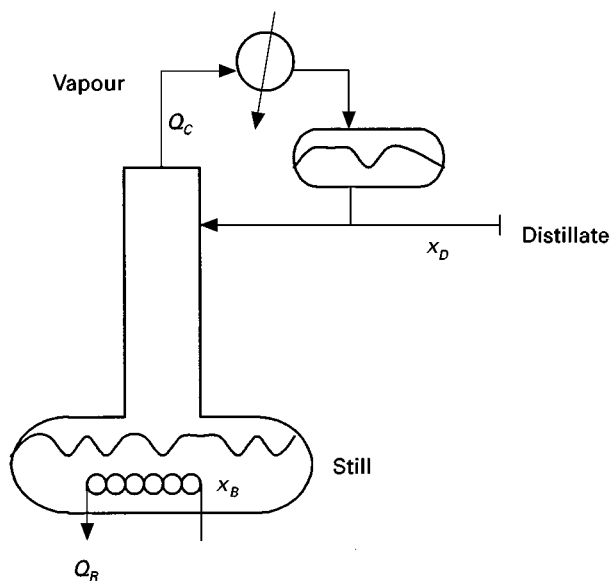

Figure 1 Simple distillation – a still.

design. For binary mixtures, these data are generally presented in the form of tables containing the liquid and vapour equilibrium compositions over a range of temperatures for a fixed pressure. The same information can also be plotted in what is called an x - y diagram. For multicomponent mixtures, however, vapour liquid equilibrium data are difficult to represent in graphical or tabular form. In such case, K values are used instead.

K value and relative volatility The K value of a component i is a measure of the tendency of such component to vaporize. A K value is defined by:

$$K_i = \frac{y_i}{x_i} \quad [2]$$

where y_i is the equilibrium composition of the vapour phase for a composition x_i of the liquid phase. K values are a function of temperature, pressure and composition, and they are widely reported for binary and multicomponent mixtures. An associated concept is the relative volatility, $\alpha_{i,j}$, which is a measure of the ease of separation of components i and j by distillation:

$$\alpha_{i,j} = \frac{K_i}{K_j} \quad [3]$$

Ideal and nonideal systems An ideal system is one in which the liquid phase obeys Raoult's Law and the vapour phase obeys the ideal gas law. For such systems, the K value is given by:

$$K_i = \frac{y_i}{x_i} = \frac{p_i^0}{P} \quad [4]$$

where p_i^0 is the vapour pressure of pure component i and P is the pressure of the system. Note that p_i^0 is a function of temperature.

For a nonideal system, the K values can also depend upon the composition of the mixture and are expressed in terms of fugacity coefficients, where ϕ_i^V is the vapour phase fugacity coefficient and γ_i^L is the liquid phase activity coefficient, as given below:

$$K_i = \frac{\gamma_i^L}{\phi_i^V} \cdot \frac{p_i^0}{P} \quad [5]$$

Azeotropic systems represent examples of nonideal mixtures for which eqn [5] has to be used.

Classification of Distillation Processes

There are many criteria under which one can classify distillation: type of accessories, operating mode,

design calculation assumptions, etc. Distillation can either be binary or multicomponent. According to the type of accessories used to increase the mass transfer in the separation process, a distillation column can be packed (use of packing) or staged (use of plates). It can be batch or continuous. Also, according to the assumptions made and accuracy expected in a distillation design calculation, a calculation technique can either be a shortcut method or a rigorous method.

Packed columns and staged columns Although simple distillation in a still historically represents the start of the distillation process, a complete separation of the components of the mixture using this process is not possible. Therefore, the application of these stills is restricted to laboratory-scale distillation, where high purities are not required or when the mixture is easily separable.

One can look at simple distillation as consisting of one equilibrium stage where a liquid and a vapour are in contact with one another and mass and heat transfers take place between the two phases. If N such stages are stacked one above the other, and are allowed to have successive vaporization and condensation, that results in a substantially richer vapour and weaker liquid (in terms of the more volatile component) in the condenser and the reboiler, respectively. This multistage arrangement is representative of a distillation column, where the vapour from the reboiler rises to the top and the liquid from the condenser is refluxed downwards (see Figure 2). The contact between the liquid and the vapour phase is established through accessories such as packing or plates. When the accessory is a stack of plates, then the result is a column of trays. Similarly, if the accessory is packing, the result is a packed column.

Continuous distillation and batch distillation The basic difference between a batch column and a continuous column is that in continuous distillation the feed is continuously entering the column, while in batch distillation the reboiler is normally fed at the beginning of the operation. Also, while the top products are removed continuously in both batch and continuous operations, there is no bottom product in a conventional batch distillation. Since in a continuous operation the total product flow equals that of incoming feed or feeds, the process reaches a steady state. In batch distillation, on the other hand, the reboiler becomes depleted over time, so the process is unsteady. Such differences are illustrated in Figure 3.

Batch distillation is a direct extension of the simple distillation still, where the Rayleigh equation

Figure 2 Equilibrium processes. (A) Single stage; (B) multi-stage.

(eqn [1]) is applicable. However, in both batch and continuous distillation, multistage mass transfer and thermodynamic equilibrium stage calculations are used for obtaining the steady-state relationship be-

tween the product composition (instantaneous in case of batch) and feed composition.

Multicomponent Multistage Equilibrium Calculations

This section is divided in two parts. In the first we discuss approximate methods (or shortcut methods); the second part corresponds to rigorous methods. The approaches are different depending upon the operation mode of the column, that is, a continuous operation or a batch operation.

In this section, our attention is focused on the approaches to the design of continuous columns. The reader can refer to the book by Diwekar (1995) for batch distillation calculations.

Shortcut Methods

Approximate methods constitute a useful for the synthesis, analysis and design of distillation separations. The main advantage of shortcut methods is that they can provide the feasible region of operation. They also provide large saving in computer time, and sometimes, they are sufficiently accurate that more expensive rigorous methods are not justified.

Concept of N_{\min} and R_{\min} Minimum number of plates, N_{\min} , and minimum reflux, R_{\min} , are very important concepts in the design of distillation processes, as they are considered to be the limiting conditions in the operation of a distillation column.

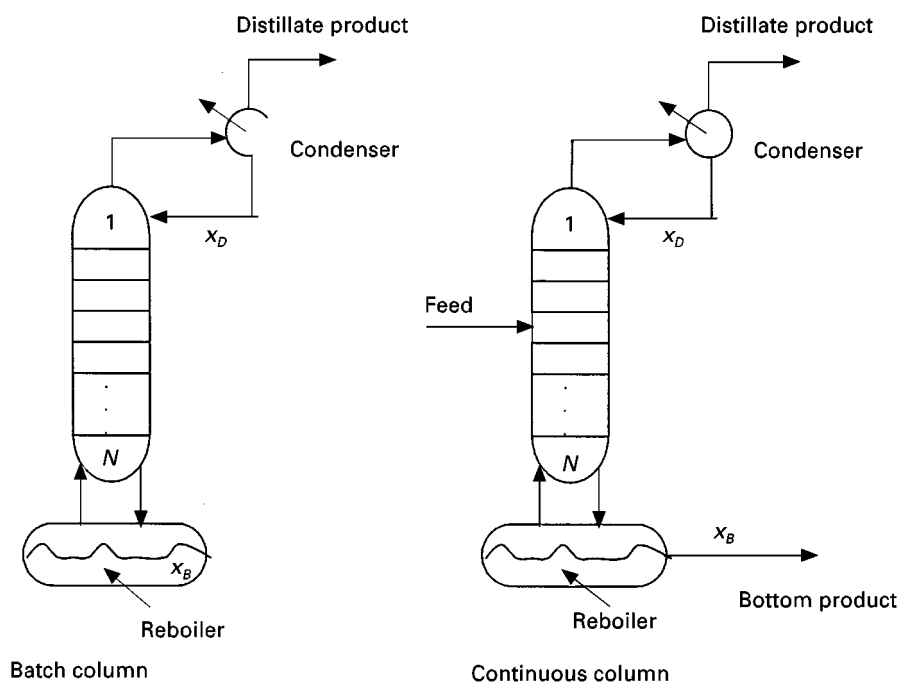

Figure 3 Batch distillation versus continuous distillation.

N_{\min} corresponds to the number of trays required for separation in a situation in which the external reflux ratio R (ratio of the liquid refluxed to the distillate rate) of the column is infinite. This corresponds to total reflux operation.

R_{\min} corresponds to the minimum value of the external reflux ratio required to achieve the specified separation in a situation in which the number of trays of the column is infinite.

Fenske–Underwood–Gilliland method The most popular of these shortcut methods is the Fenske–Underwood–Gilliland method (FUG). The basic assumptions of such a method are:

1. The system is ideal.
2. Constant molar overflow (as in the McCabe Thiele method for binary mixtures).
3. The separation is essentially taking place between the light key component and the heavy key component. The light key (lk) is the lightest component appearing in the bottom and the heavy key (hk) is the heaviest component appearing in the top.

In the FUG method:

1. Fenske's equation is used to calculate the minimum number of trays, N_{\min} .
2. Underwood's equation is used to estimate the minimum reflux, R_{\min} .
3. Gilliland's correlation is used to calculate the actual number of trays, N (for any R given), or the reflux ratio, R , (for any N given) in terms of previous limiting values N_{\min} and R_{\min} .

The Fenske equation is:

$$N_{\min} = \frac{\log \left[\left(\frac{x_{Dlk}}{x_{Blk}} \right) \cdot \left(\frac{x_{Bhk}}{x_{Dhk}} \right) \right]}{\log(\alpha_{lk,hk})} \quad [6]$$

where $\alpha_{lk,hk}$ is the relative volatility between the light key component and the heavy key component. Since it can be expected that the value of α changes for each tray of the column, the geometric average of this value is generally used:

$$\alpha^N = \alpha^N \cdot \alpha_{N-1} \dots \alpha_1 \quad [7]$$

The Underwood equation can be written as:

$$\sum_i \frac{\alpha_i \cdot x_{i,D}}{\alpha_i - \theta} = R_{\min} + 1 \quad [8]$$

where θ is a root of the equation:

$$\sum_i \frac{\alpha_i \cdot x_{i,F}}{\alpha_i - \theta} = 1 - q \quad [9]$$

such that $\alpha_{hk} \leq \theta \leq \alpha_{lk}$. α_{hk} and α_{lk} are the relative volatilities of the key components (light and heavy) in the calculation. As stated earlier, such components are the ones that the designer uses as the basis for the separation.

Finally, the Gilliland correlation is given by:

$$\frac{N - N_{\min}}{N + 1} = 1 - \exp \left[\left(\frac{1 + 54.4G}{11 + 117.2G} \right) \cdot \left(\frac{G - 1}{G^{0.5}} \right) \right] \quad [10]$$

where

$$G = \frac{R - R_{\min}}{R + 1} \quad [11]$$

The main assumptions of the Underwood equation are the assumption of constant molar flow rates and an ideal system. Such assumptions constitute the main limitation of the algorithm.

Rigorous Methods

Recent developments in computer hardware and software have made it possible to use rigorous methods for the design of distillation processes. In these methods, the assumption of constant molar flow rates is no longer considered. The implication of removing such an assumption is that rigorous methods not only consider mass balances, but also enthalpy balances for each of the trays of the column. Thus, rigorous methods require simultaneous convergence of mass and energy equations. Depending on the calculation sequence, there are several rigorous methods reported in the literature. The most important of these methods are: (1) Thiele–Geddes; (2) tridiagonal methods; (3) Naphtali–Sandholm; (4) inside-out algorithms; (5) Θ convergence methods; and (6) $2N$ Newton methods. The method of Naphtali–Sandholm and the inside-out algorithm, which are commonly used nowadays, are discussed in this work to give an idea of the scope and applications of rigorous methods.

MESH equations Most rigorous methods involve the solution of the so-called MESH equations. For each stage n in a distillation column (and for each component i in a mixture of C components), the equations representing mass balance (M), equilibrium relationships (E), summation of compositions (S) and energy balance (H), constitute the MESH equations. In addition, both K values and enthalpies

are generally given as functions of temperatures, pressures and compositions. The generalized form of the MESH equations for the equilibrium stage shown in Figure 4 and the expressions for K values and enthalpies are present in Table 1.

Naphtali-Sandholm method In the Naphtali-Sandholm method, the number of variables of the MESH equations is reduced by the introduction of component flow rates and side streams. Furthermore, the summation of compositions are eliminated. Those modifications result in the equations presented in Table 2.

To solve the system of MESH equations given in Table 2, the vectors of variables and equations are ordered as follows. Variables:

$$\bar{X} = [\bar{X}_1, \bar{X}_2, \dots, \bar{X}_n, \dots, \bar{X}_N] \quad [12]$$

where N is the number of stages and

$$\bar{X}_n = [v_{n,1}, v_{n,2}, \dots, v_{n,C}, T_n, l_{n,1}, l_{n,2}, \dots, l_{n,C}]^T \quad [13]$$

Equations:

$$\bar{F} = [\bar{F}_1, \bar{F}_2, \dots, \bar{F}_n, \dots, \bar{F}_N] \quad [14]$$

where

$$\bar{F}_n = [\hat{H}_n, M_{n,1}, M_{n,2}, \dots, M_{n,C}, E_{n,1}, E_{n,2}, \dots, E_{n,C}]^T \quad [15]$$

The solution process is iterative, using one of the several variations of the Newton method. Thus, corrections at each iteration k are obtained from

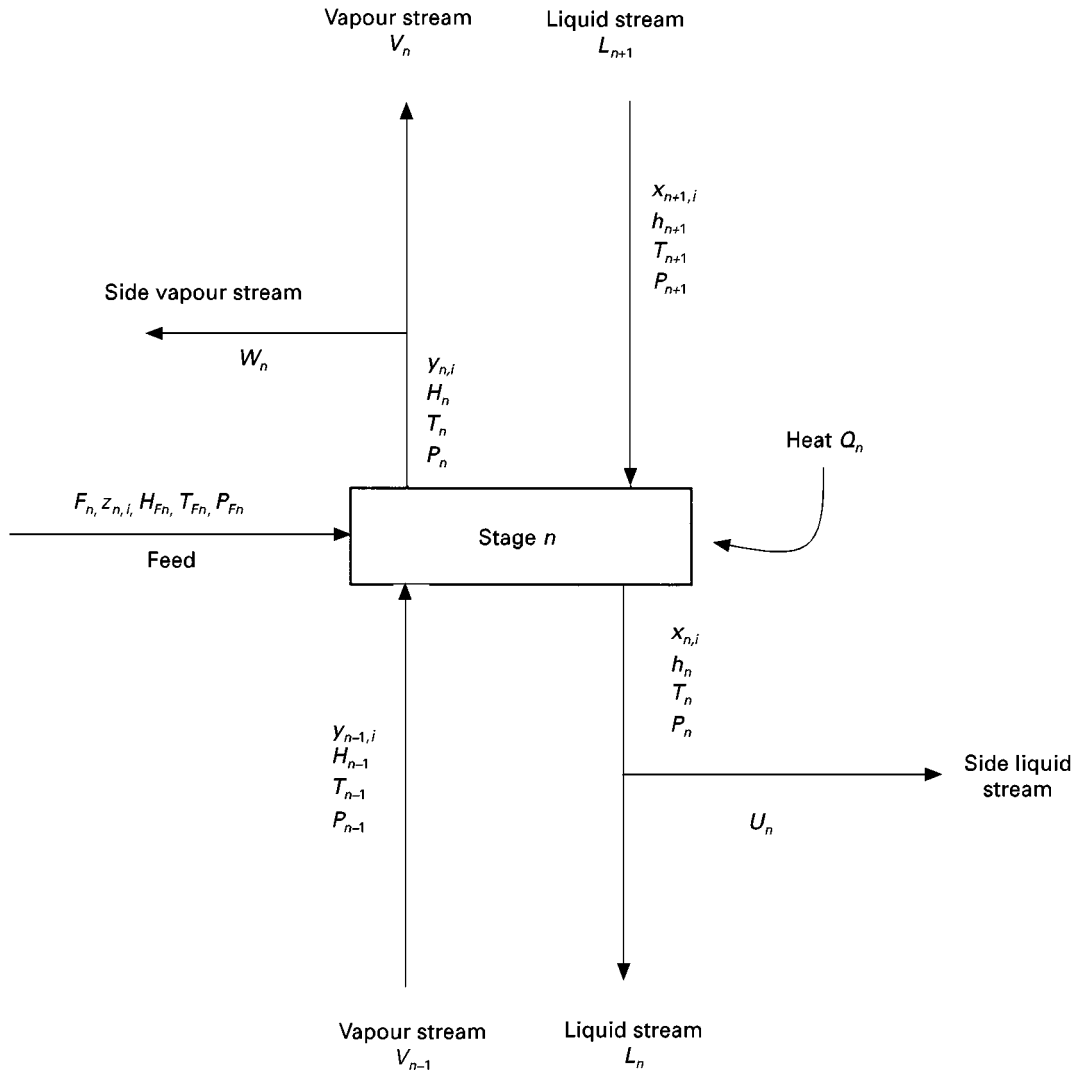

Figure 4 Equilibrium stage. Derivation of MESH equations.

Table 1 MESH equations

Relationship	Equation
Mass balance	$L_{n+1} \cdot x_{n+1,i} + V_{n-1} \cdot y_{n-1,i} + F_n \cdot z_{n,i} - (L_n + U_n) \cdot x_{n,i} - (V_n + W_n) \cdot y_{n,i} = 0$
Equilibrium	$y_{n,i} = K_{n,i} \cdot x_{n,i}$
Summation of compositions	$\sum_i y_{n,i} - 1 = 0$
H energy balance	$L_{n+1} \cdot h_{n+1} + V_{n-1} \cdot H_{n-1} + F_n \cdot H_{F_n} - (L_n + U_n) \cdot h_n - (V_n + W_n) \cdot H_n - Q_n = 0$
K values and enthalpies	$K_{n,i} = K_{n,i}(T_n, P_n, x_n, y_n)$
	$H_{n,i} = H_{n,i}(T_n, P_n, y_n)$
	$h_{n,i} = h_{n,i}(T_n, P_n, x_n)$

(classical Newton–Raphson equations):

$$\Delta \bar{F}^{(k)} = - \left[\left(\frac{\partial \bar{F}}{\partial \bar{X}} \right)^{-1} \right]^{(k)} \cdot \bar{F}^{(k)} \quad [16]$$

$$\bar{X}^{(k+1)} = \bar{X}^{(k)} + t \cdot \Delta \bar{X}^{(k)} \quad [17]$$

where t is such that $0 \leq t \leq 1$. t is the factor that ensures progress toward the solution of the system at equations of each iteration.

Inside-out algorithm In the Naphtali–Sandholm method, the temperatures and component flowrates are the primary solution variables (see eqn [13]) and

are used to generate the K values and enthalpies from complex correlations. Hence, such a method updates the primary variables in an outer loop, with the K values and enthalpies updated in an inner loop whenever the primary variables change.

In inside-out algorithms, the previous situation is reversed. These methods use complex K values and enthalpy correlations to generate parameters for simple K values and enthalpy models. Hence, these parameters become the variables for the outside loop. The inside loop then consists of the MESH equations. In every step through the outside loop, the simple K values and enthalpy models are updated by using the MESH variables from the inside loop. This sets up the next pass through the inside loop. The book by Kister (1992) provides detailed guidelines for the use of the various inside-out methods.

Table 2 MEH equations for method of Naphtali and Sandholm

Relationship	Equation
Component flow rates and side streams	$v_{n,i} = y_{n,i} \cdot V_n$
	$l_{n,i} = x_{n,i} \cdot L_n$
	$f_{n,i} = z_{n,i} \cdot F_n$
	$s_n = U_n/L_n$
	$S_n = W_n/V_n$
M	$M_{n,i} = l_{n,i} \cdot (1 + s_n) + v_{n,i} \cdot (1 + S_n) - l_{n+1,i} - v_{n-1,i} - f_{n,i}$
E	$E_{n,i} = K_{n,i} \cdot l_{n,i} \cdot \left(\sum_k v_{n,k} / \sum_k l_{n,k} \right) - v_{n,i} = 0$
H	$\hat{H}_n = h_n \cdot (1 + s_n) \cdot \sum_i l_{n,i} + H_n \cdot (1 + S_n) \cdot \sum_i v_{n,i} - h_{n+1} \cdot \sum_i l_{n+1,i} - H_{n-1} \cdot \sum_i v_{n-1,i} - H_{F_n} \cdot \sum_i f_{n,i} - Q_n = 0$

Special Separations

When the components of a mixture have low relative volatilities, or when the mixture contains a large number of components, separation by distillation becomes difficult and expensive because a large number of trays or a large number of columns are required for the separation. Furthermore, some systems may show nonideal behaviour such as the formation of azeotropes or a reversal of the relative volatility with the change in pressure from top to bottom in a column. Complex systems which have these characteristics are common in the pharmaceutical and synthetic chemical industry.

This section presents a brief review of separations in which the traditional distillation process is altered, but the general principles of multicomponent distillation still apply. Three broad categories of such special separations exist: azeotropic distillation, extractive distillation and reactive distillation. Petroleum distillation will also be discussed since it represents a case

in which the complexity of the mixture (petroleum) requires special considerations for the separation.

Azeotropic Distillation

Highly nonideal systems, with components having close boiling points among them, often produce azeotropes. Azeotropes can be identified by using an x - y diagram. When an azeotrope is present, the equilibrium curve crosses the line $x = y$ (45° line), as shown in Figure 5.

Azeotropes limit the separation that can be achieved by conventional distillation. Sometimes it is possible to shift the equilibrium by changing the pressure of the system sufficiently to move the azeotrope away from the region where the separation must be made. Other cases, however, require the addition of a new material in order to achieve separation.

In azeotropic distillation, the equilibrium behaviour of the mixture is modified by adding a new material (called the solvent or entrainer). The added entrainer forms a minimum boiling point azeotrope with one or more components and distils overhead. The distillate is generally heterogeneous, that is, it is composed of two immiscible liquids when condensed. Such a heterogeneous nature facilitates the separation of the product from the entrainer.

Extractive Distillation

Extractive distillation also involves the addition of the third component to the mixture (solvent or entrainer). However, in the case of extractive distillation, the solvent is a relatively high boiling point material, which is present at high concentration on each stage and exits at the bottom. To improve the efficiency of the process, the entrainer has to be added

at the top of the column, so that its concentration on each stage will be enough to produce the desired effect in the equilibrium of the original mixture. Finally, the entrainer is separated from the bottoms product in another distillation column.

Reactive Distillation

The idea of combining reaction and separation in a single apparatus has been extensively investigated. Doherty and Buzad (1992) present a survey of the available design techniques for reactive distillation. Reactive distillation is particularly attractive whenever a chemical reaction provides the favourable effect of reacting away azeotropic mixtures so that the behaviour of the liquid phase is simplified. In addition, it has been shown that reactive distillation has the potential of eliminating recycle costs when a liquid reaction involves a large excess of one reactant.

In general, the current trend in reactive distillation design is using experimental results from bench-scale problems in the initial stages of the design, and then using computer-aided simulation tools for scale-up and operability issues.

Possible profitable applications of reactive distillation processes are numerous. However, an incomplete understanding of the interactions of the many nonlinear phenomena such as chemical reaction, phase equilibrium, mass transfer and countercurrent flow has prevented the widespread use of such processes. Considerable research effort in the area is currently being conducted.

Petroleum Distillation

Petroleum distillation is particularly difficult because of the large number of components of the mixture and large scale of the processes. This type of distillation involves products that are not easily identifiable components. Instead, separation is achieved in terms of pseudo-components, which are generally characterized in terms of their true boiling point ranges (TBP), an average relative molecular mass and an API gravity. TBP data are widely available and are generally presented in form of curves.

There are two main approaches to the design of petroleum distillation columns. The first consists of the solution of mass and energy balances based on empirical correlations, and is basically a calculation by hand. This approach was developed by Packie.

In the second approach, each pseudo-component is characterized for properties (such as vapour pressure and enthalpy) by using homologous-series approaches. Thus, rigorous mass and energy balances can then be applied to determine the separation in

Figure 5 Azeotropic behaviour.

terms of the reflux ratio. Several efficient computer programs following this approach have been developed.

Packed Columns

Several approaches exist for the design of packed columns. These are based on the concepts of number of transfer units (NTU), height of transfer units (HTU) and height equivalent to a theoretical plate (HETP). The last of these concepts is the most widely used.

Since methods for the design of staged distillation columns are well developed, a common approach is to calculate the number of trays N using such approaches and then to find the height of the packed column, h , by the relation:

$$h = N \cdot \text{HETP} \quad [18]$$

There exist various correlations for predicting the value of the HETP. One of most commonly used is the Sherwood correlation. It can be expected that HETP will change with respect to the operating conditions, physical properties of the liquid, etc., so, it is calculated in terms of correlations containing many factors.

Nonequilibrium Distillation

All the mathematical methods (binary, rigorous, shortcut) presented earlier assume that each stage in the column is an equilibrium stage. In reality, however, this assumption is rarely satisfied.

Stage Efficiency

An approach to nonequilibrium calculations is the use of the concept of stage efficiency. The most common approach is to modify the rigorous methods with the introduction of the so-called Murphree efficiency in the calculations. The Murphree efficiency in a stage calculation can be defined as:

$$E_{M_i}^L = \frac{x_{out,i} - x_{in,i}}{x'_i - x_{in,i}} \quad [19]$$

for the liquid and

$$E_{M_i}^V = \frac{y_{out,i} - y_{in,i}}{y'_i - y_{in,i}} \quad [20]$$

for the vapour. x'_i are the compositions of the liquid that would be in equilibrium with the outlet composition of the vapour. y'_i are the compositions of the

liquid that would be in equilibrium with the outlet composition of the liquid.

Mass Transfer Rates

It has been shown that stage efficiency prediction and scale-up are difficult and unreliable. For highly nonideal, polar and reactive systems, a transport phenomena approach for predicting mass transfer rates is preferred. Such mass transfer rates are calculated continuously along the column similarly to the HETP calculation for packed columns.

Nonequilibrium models for the calculation of mass transfer rates assume that, while the bulk vapour and liquid phase are not in equilibrium with each other, there is an equilibrium at the interface. Hence, the net loss or gain for a component at the interface is expressed in a rate form. For instance, the net gain by the vapour because of the transfer at the interface is:

$$N_{ij}^{V0} = N_{ij}^V \cdot da_i \quad [21]$$

where N_{ij}^V is the vapour flux of the component at some point through the interface and da_i is the interface area through which the flux passes. The mass transfer rates for liquid and vapour, N_{ij}^V and N_{ij}^L , are dependent on the mass transfer coefficients for each phase. There exist several correlations for the heat and mass transfer coefficients and these are dependent on the compositions in the bulk phase, the temperatures in the bulk phase and interface, and on the packing or tray geometries.

Industrial Applications

Distillation is by far the most widely used separation technique in the petroleum, natural gas and chemical industries so, applications of multicomponent distillation are numerous. A couple of industrial applications are described in this section.

Primary Distillation of Crude Oil

A typical configuration for the distillation of a crude oil unit includes two main columns, an atmospheric tower and a vacuum tower (see Figure 6). In the atmospheric tower, crude oil is rectified (at a pressure no greater than 275.8 kPa (40 psi); to yield a distillate product containing light hydrocarbon gas, light and heavy naphtha, kerosene, diesel oil, and a bottom product of heavier components (TBP greater than 420°C). Each of the side streams of the atmospheric tower are sent to side strippers that have a partial reboiler or steam stripper. The side stream strippers serve to remove the light components. Stripping by

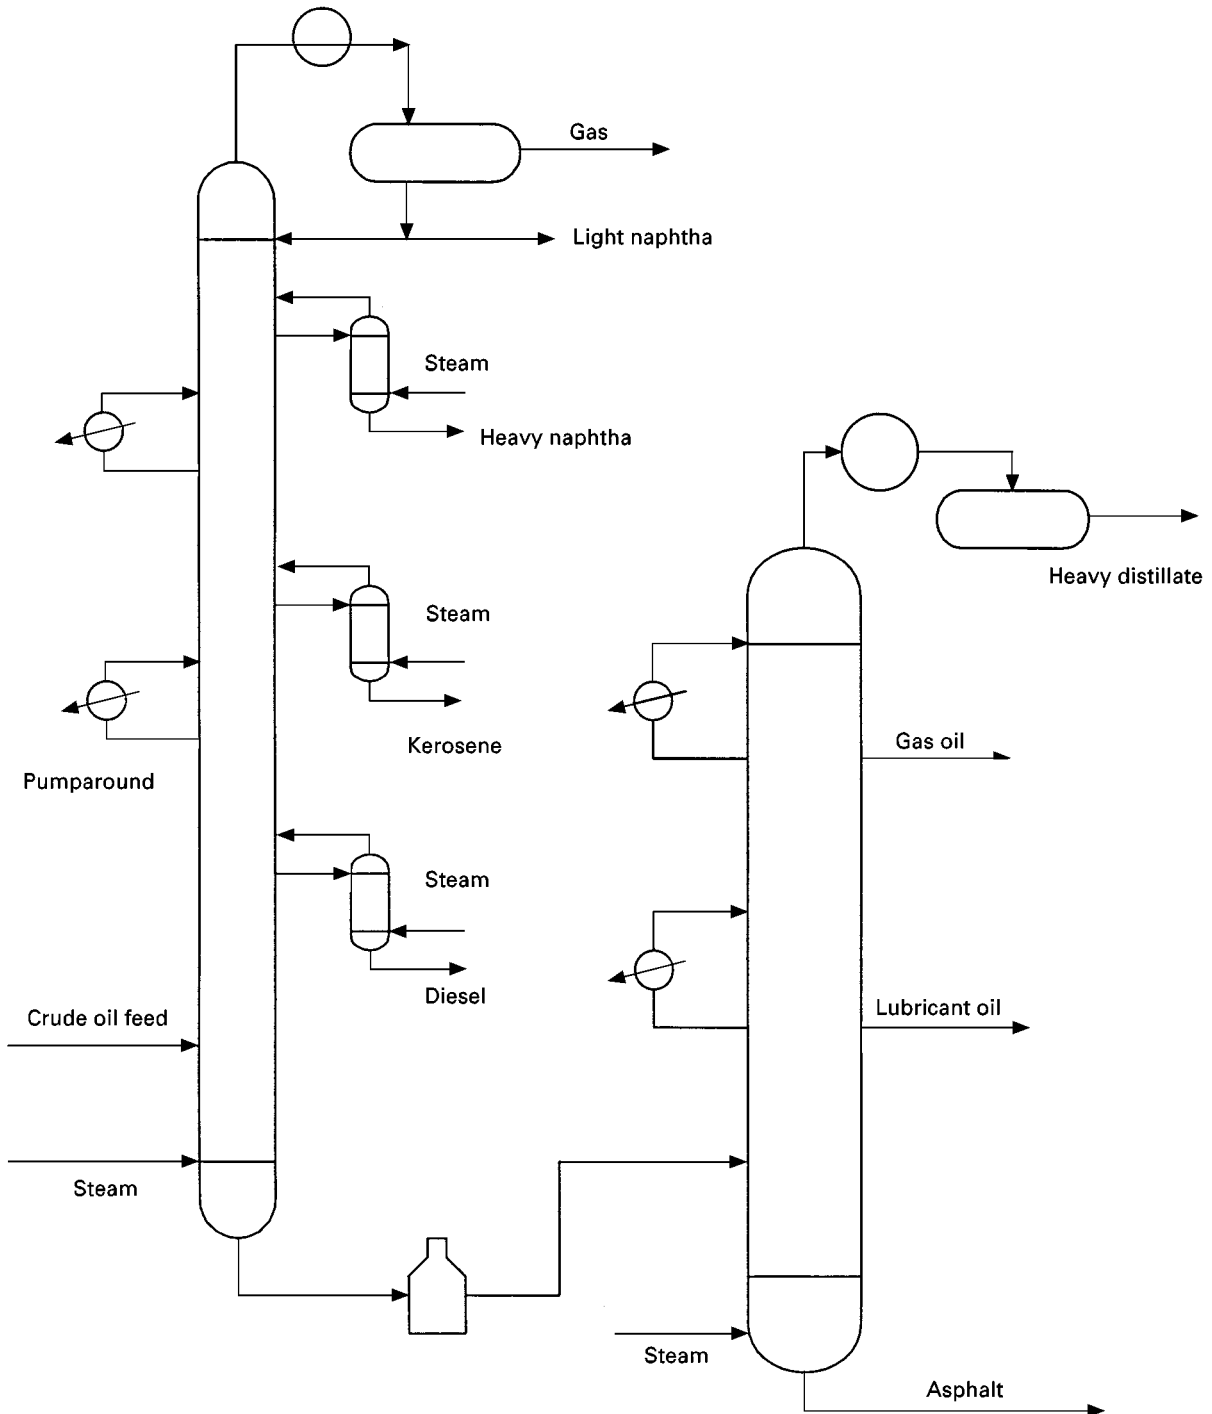

Figure 6 Crude oil distillation unit.

steam is also frequently used in the bottom of the tower.

The bottom product of the atmospheric tower is further separated by rectification in the vacuum tower. The feed-tray pressure of a vacuum tower is usually 6 kPa (45 Torr). Vacuum towers are mainly designed to obtain heavy distillates such as gas oil,

lubricating oils and bunker fuels with asphalt as the bottom product.

The pump-around systems shown in both of the towers serve to make much larger liquid flows on the intermediate stages and produce a net increase in liquid flow. This serves as a point of control to keep the plates from running dry.

Highly developed procedures for the preliminary design of fractionators that process petroleum are commercially available through computer programs. The program 'REFINE' of the ChemShare Corporation and the 'PROCESS' (now PRO-II) program of Simulation Sciences Inc. are two examples.

Ethylene and Propylene Production

The manufacture of ethylene and propylene is one of the most important operations of the petrochemical industry. In that process, ethylene and propylene are formed from the thermal cracking of other hydrocarbons, such as ethane, propane and naphtha. The mixture resulting from the thermal cracking is very complex. Hence, the mixture has to be separated into relatively pure ethylene and propylene, ethane and propane to be used as a recycle, methane and hydrogen to be used as fuel, and heavier products to be used for gasoline. A typical refinery gas feed to the separation system of this process contains hydrogen, ethylene, methane, ethane, propane, propylene and lower compositions of other heavy hydrocarbons. The distillation sequence most commonly used for the separation of the mixture is shown in Figure 7.

In a high pressure plant (no refrigeration is needed for condensation of products), the distillation sequence consists of five distillation columns:

1. Demethanizer
2. Deethanizer
3. Ethylene/ethane separator
4. Depropanizer
5. Propylene/propane separator.

Both the propylene/propane and the ethylene/ethane separator require high towers with large diameters because such mixtures contain components with very close relative volatilities. A plant that uses the configuration described here was built by Pullman Kellogg Inc., Houston, Texas.

In the case of a lower pressure plant, the deethanizer precedes the demethanizer because refrigeration is required for the feed of the demethanizer. So, by placing the deethanizer first, important utility savings are obtained.

Future Work

Enormous progress has been made on the application and design of distillation technology. However, challenges still exist in some areas, which lead to the following ongoing research:

1. Improvement of mass transfer coefficients in packed distillation columns. Great effort is being made on the design of efficient packings and accurate correlation of their performance.

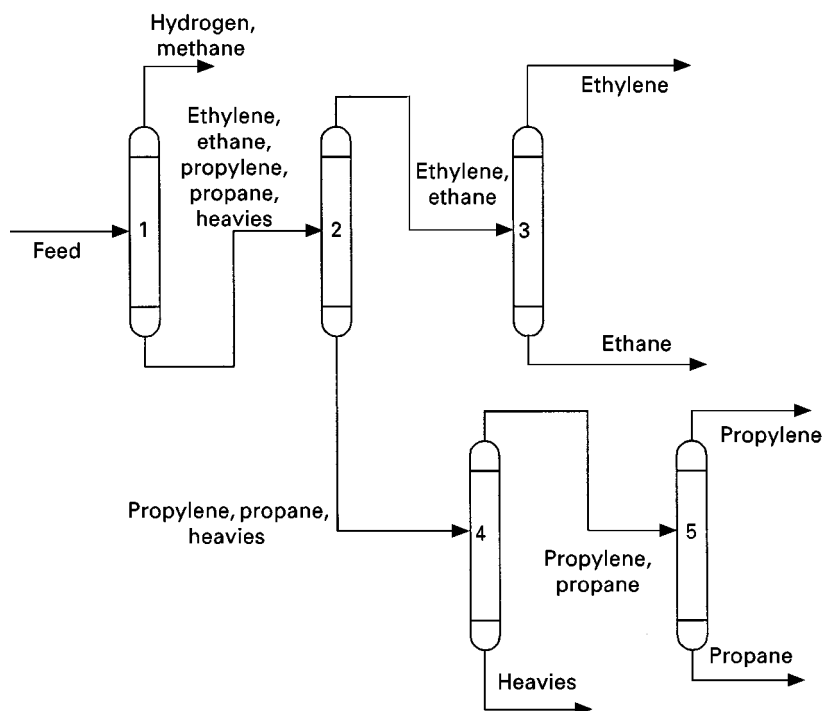

Figure 7 Separation of products of the manufacture of ethylene and propylene.

2. The simulation, synthesis and design of reactive and azeotropic distillation. Such topics still constitute a gap in the knowledge of distillation technology.
3. Investigation of complex configurations for batch distillation processes.
4. Use of optimization methods for obtaining optimal configuration and design of batch and continuous distillation processes.
5. Online optimization and control of columns.

Use of Packing in Distillation

Use of packing in mass transfer has its origins in the early 1800s for simple applications such as alcohol distillation, and in sulfuric acid plant absorbers. Glass balls, coke or even stones were used as packing materials. Nevertheless packings for distillation were not established until the 1930s with the use of regular shape materials such as ceramic Raschig rings and Berl saddles, as well as the availability of distillation calculations such as the McCabe–Thiele and Ponchon–Savarit methods. Early in the second half of the century, the use of packing for distillation went through a transformation, producing the second-generation packings (see Table 1). Regular and improved shape of packings, such as pall rings, became available with larger open areas that permitted a substantial increase both in capacity and column efficiency. In the 1960s Sulzer introduced the wire-mesh packings with very high efficiency (low height equivalent to a theoretical plate, HETP), resulting in a new transformation in the use of packings. In the 1970s

and 1980s all major mass-transfer equipment manufacturers developed structured packings. Compared to the traditional tray columns spectacular improvements in plant capacity were achieved, but also some projects were pitfalls, when the expected benefits did not materialize. Manufacturers started realizing that liquid distributors had to be improved, but there was no coherent understanding, nor correlations, that could lead to a safe distributor-column system design. Many manufacturers returned to trays, producing new improved designs, using the area under the downcomer for vapour flow: these trays are offered with new names that indicate their increased vapour flow capacity (Maxyflow, Superfrack, etc.). The need for good distribution and its effect on the column efficiency are now well understood, allowing safe design and efficient applications for random and structured packings in large industrial columns.

General Concepts

Distillation separation is based in relative volatility that makes it possible to concentrate the more volatile components in the vapour phase while the less volatile ones remain in the liquid phase. Distillation columns are countercurrent vapour-liquid mass-transfer devices, where the required separation and purification of components is achieved.

Table 1 Evolution of packing

^bDeveloped by Leva, marketed by Nutter.

^cVariations of these grids are now offered by most packing manufacturers.

^dDeveloped by Sulzer, they are now offered by other manufacturers.

The main variable influencing the column design requirements is the relative volatility, α . **Figure 1** illustrates the effect of α on the column performance:

- As α increases, the number of theoretical stages (NTS) required to achieve a fixed product quality decreases, since NTS is proportional to $1/\ln(\alpha)$. As α decreases and approaches 1, the number of stages required increases approaching infinity. At any given α , the minimum number of stages required to achieve a given separation corresponds to a total reflux operation. At total reflux all overhead vapours are condensed and returned to the column as

reflux, so that there is no net product. The minimum reflux sets the limiting slope of the operating line, required to achieve a given separation.

- At constant α , the NTS increases as the product purity increases. The increase is proportional to the logarithm of the key components purity ratio.

It can be also demonstrated that:

- At constant product purity, the minimum reflux decreases as α increases.
- At constant product purity, the minimum number of stages decrease as α increases.
- At constant α , the minimum reflux decreases as the product purity decreases.

**Figure 1** Number of stages required vs. relative volatility at several product purities.

- At constant α , the minimum number of stages increases as the product purity increases.

All these statements say that α defines the separation difficulty. For values around 1.1 and lower, separation by distillation becomes very difficult, requiring very large and expensive columns. For $\alpha = 1$ the mixture is azeotropic and would require the addition of selective entrainers if azeotropic or extractive distillation is to be applied.

Packed Column Description

Figure 2 illustrates a tower with structured packing. In addition to the packing itself, packed columns require other internals to assure the performance of the packing. These internals are:

- Liquid feed pipes to deliver the fluid to the liquid distributors, as seen at the top of the tower and at the intermediate distributor.
- Liquid collection and mixing as shown below the top bed.
- Liquid draw-off sump and pipe as shown below the top bed.
- Liquid redistributors, as presented between the two beds.
- Vapour feed pipes as shown at the vapour inlet nozzle, at the bottom of the tower.
- Packing support plates resting on beams and levelled rings welded to the vessel.
- Hold-down plates.

Incorrect design or incorrect installation of any of these elements can lead to tower failure. One of the most critical elements, and often the culprit of tower failures, is the liquid distributor.

Packing Selection

Figures 3 and 4 illustrate random and structured packings. There are many parameters to be considered in the selection of packings; in some cases, there are one or two considerations that dictate the selection, such as capacity for a revamp, which could favour structured packing. There are also some considerations or applications, such as high-pressure distillation, that could make structured packing a questionable choice. Table 2 gives some general guidelines on packing selection.

Pressure Drop in Packed Beds

The dry-bed pressure gradient is given by the following equation:

$$\Delta P_d = C_1 \rho_g u_g^2 \quad [1]$$

Figure 2 Packed tower illustration. (Photo courtesy of Sulzer Chemtech.)

Figure 3 Random packings: (A) IMTP®. (Photo courtesy of Norton Chemical Process Products Corporation.) (B) Nutter Ring®. (Photo courtesy of Sulzer Chemtech.) (C) Cascade Mini-Rings® (CMR™) and Fleximax®. (Courtesy of Koch-Glitsch Inc.) (D) Pall Rings metal and plastic. (Courtesy of Koch-Glitsch Inc.)

Leva extended the correlation to irrigated beds:

$$\Delta P_i = C_1 10^{\beta u_1} \rho_g u_g^2.$$

Robbins developed the following set of general pressure-drop correlations:

$$\Delta P = C_2 G_f^2 10^{C_3 L_f} + 0.4(L_f/20\,000)^{0.1} (C_2 G_f^2 10^{C_3 L_f})^4 \quad [2]$$

where:

$$G_f = G(0.075/\rho_g)^{0.5} (F_p/20)^{0.5} 10^{0.024 \rho_g} \quad (\text{for pressures over 1 atm})^*$$

*Note: in this correlation the original term $10^{0.3 \rho_g}$ was replaced by $10^{0.024 \rho_g}$ since the original correlation predicts too high a pressure drop.

Figure 4 Structured packings: (A) Wire gauze structured packing. Close view, packing and wiper bands. (Photo courtesy of Koch-Glitsch Inc.) (B) Two structured packing layers rotated 90°. (Photo courtesy of Koch-Glitsch Inc.) (C) One structured packing element for small towers. (Photo courtesy of Sulzer Chemtech.) (D) Structured packed bed for a small tower. Figure 4 Continued

$$L_f = L(62.4/\rho_1)(F_p/20)^{0.5}\mu_1^{0.1} \text{ (for } F_p \text{ over 15)}$$

$$C_2 = 7.4 \times 10^{-8} \text{ and } C_3 = 2.7 \times 10^{-5}$$

For the case of dry packing $L_f = 0$, the pressure-drop equation reduces to:

$$\Delta P = C_2 G_f^2 = C_2 (0.075/20) F_p G^2 / \rho_g. \quad [3]$$

Figure 5 presents a family of pressure drop-lines at constant liquid flow as a function of the vapour flow. The constant liquid rate lines start parallel to the

Figure 5 Bed ΔP vs. rates. (Permission from Gulf Publishing Company.)

dry-column line (which is a function of the drag only). Equation [3] allows calculation of the packing factor, F_p , by measuring the slope of the dry-packing pressure-drop data. As the vapour rate increases, the slope of the constant liquid rate lines increase; this increase is also proportional to the liquid rate. The initial departure from the dry-line slope indicates interaction between the vapour and liquid, and represents a loading point. Efficient mass-transfer operations can be achieved only above the loading

Application rating: 1, best; 2, good; 3, fair; 4, poor.

^aEfficiency may be reduced at high capacities.

^bAs may be required based on corrosion protection considerations, such as ceramic.

^cSystems below 5 gallons min⁻¹ ft⁻².

^dSystems over 15 gallons min⁻¹ ft⁻².

^eApplies to sieve trays, specially dual-flow, not to valve trays.

^fIt would require a fouling-resistant distributor, which may result in reduced efficiency.

point. For any given liquid rate, as the vapour rate further increases, the pressure-drop line slope increases rapidly until the line becomes near vertical. At this point the flow and ΔP are unstable, and the bed is flooded; the vapour flow does not allow the liquid to flow down the bed and there is massive entrainment of liquid in the vapour phase and mass transfer is no longer viable.

For most packings, bed flooding occurs between 1 and 2 inches of water-pressure drop per foot of packing. Pressure drop at flooding seems to be a function of the packing size. Kister cited Zenz and later Strigle and Rukovena observations indicating that flooding (ΔP_f) is higher for smaller size packings, and proposed a correlation to determine the pressure drop at flooding as a function of the packing factor.

$$\Delta P_f = 0.115(F_p)^{0.7} \quad [4A]$$

We also obtained by regression from data published by Strigle:

$$\Delta P_f = 0.146F_p^{0.75} \text{ inch liquid ft}^{-1} \text{ or} \quad [4B]$$

$$\Delta P = 0.146S_g F_p^{0.75} \text{ inch H}_2\text{O ft}^{-1} \quad [5]$$

Pressure drop at incipient loading may be estimated:

$$\Delta P_l = 0.072S_g F_p^{0.75} \quad [6]$$

and pressure drop at maximum efficiency loading may be estimated by:

$$\Delta P_e = 0.082S_g F_p^{0.75} \quad [7]$$

All the above correlations have been regressed for metallic random packings (Pall Rings and IMPT®).

For column design, it is well-accepted practice to assume flooding at 1 inch of water per foot of packing pressure drop and design the packing for an operation at 80% flood. However, when reliable packing-factor information is available, the use of the calculated ΔP_f , using one of the eqns [4A], [4B] and [5], is a more accurate approach.

Caution: Presence of foam, even incipient foam, has a great impact on a packing column pressure drop and performance and should be avoided. Amines, insoluble fine solids (such as corrosion products), high-viscosity organic liquid (0.5–1 cP or higher) and immiscible liquids are known to foam. For these systems, or other systems known to be prone to foam, continuous or intermittent dosing of antifoam agents may be required to maintain an efficient packed-column operation. Nevertheless, uncontrol-

led antifoam injection is known to aggravate foaming problems. Filtration of liquids and adsorption of contaminants on activated carbon has proven valuable to control foaming in some systems such as amines.

Flooding Correlations

Several generalized flooding and pressure-drop correlations have been proposed for commercial packings. Sherwood, Shipley and Holloway presented the first correlation between a 'flow parameter' X defined as:

$$X = (L/G) (\rho_g/\rho_l)^{0.5} \quad [8]$$

and a 'flooding parameter' Y defined as:

$$Y_f = (u_g^2/g_c)(a/\varepsilon^3)(\rho_g/\rho_l)\mu^{0.2} = (G_f^2/g_c)(a/\varepsilon^3)\mu^{0.2}/(\rho_g\rho_l). \quad [9]$$

Sherwood and co-workers correlated dumped and stacked random packing data and found that Y_f is around five times higher for stacked than for dumped packing, which means that mass velocity at flood is over two times higher for stacked packing. This was the precursor idea for the later development of 'structured' packings.

Lobo and Friend presented a similar correlation of Y and X with indication of pressure-drop lines and flooding line.

Leva proposed a similar correlation with the same flow parameter given by eqn [8] and modified the flooding parameter $Y_f = (G_f^2/g_c)(a/\varepsilon^3)\mu^{0.2}(\rho_w/\rho_l)^2/\rho_l$. According to this correlation, minimum loading Y_m occurs at about one-third of Y_f which means that loading starts at 50% of the mass flow rates corresponding to the flooding point.

Eckert observed that the packing geometrical properties factor (a/ε^3) did not represent correctly the packing in the flooding correlations. He introduced a packing factor, F_p . The value of F_p is determined experimentally from pressure-drop data. The new flooding parameter became:

$$Y_f = (G_f^2/g_c)F_p\mu^{0.2}(\rho_w/\rho_l)^2/(\rho_g\rho_l) \quad [10]$$

and is correlated to the same flow parameter $X = (L/G) (\rho_g/\rho_l)^{0.5}$.

The most recent proposed correlation was presented by Strigle (see Figure 6):

$$Y = C_s F_p^{0.5} (\mu/S_g)^{0.05} = C_s F_p^{0.5} v^{0.05} \quad [11A]$$

Figure 6 Strigle pressure drop chart. (Permission from Gulf Publishing Company.)

Y is the vapour flow parameter and is a function of vapour capacity factor $C_s = u_g(\rho_g/(\rho_l - \rho_g))^{0.5}$, the packing factor and the kinematic viscosity $v = \mu/S_g$. Note that at flooding $Y = Y_f$. Y is plotted in a linear ordinate as a function of the flow parameter X in a logarithmic abscissa and a family of constant ΔP lines. No flooding line is shown. The advantage of the linear ordinate is that it is easier to interpolate than the older log-log charts.

Figure 7 presents the flooding lines of packings as a function of the packing factor F_p and the flow parameter X . The ordinate is the modified flooding parameter Y_f^* , defined as follows:

$$Y_f^* = Y_f/F_p^{0.5} = C_s v^{0.05} \quad [11B]$$

Y_f^* is plotted as a function of the flow parameter X , eqn [8], at constant packing factors.

Figure 7 Modified flooding parameter as a function of the flow parameter.

Comparing Packed Column vs. Tray Tower Capacity

Table 5 presents packing capacities, calculated from the above relations, compared to tray flooding capacities at several tray spacings.

Packed Tower Diameter

Figures 6 or 7 can be used to determine the column diameter. Using Figure 7 the procedure is as follows:

1. Determine the value of the abscissa $X = L/G(\rho_g/\rho_l)^{0.5}$.
2. Obtain from the manufacturer the selected packing F_p value, or from Tables 3 or 4.
3. Determine the ordinate $Y_f^* = C_s v^{0.05}$ from Figure 7.
4. Calculate the capacity factor at flood C_s from the Y_f^* value, the gas velocity at flood $u_g = C_s(\rho_l - \rho_g)^{0.5}/\rho_g$ and the flooding gas mass velocity $G_{fl} = u_g \rho_g$.
5. Determine the column cross-sectional area $A_c = V/(0.8G_{fl})$, based on 80% of the G flooding rate. This is standard design practice for new column sizing, and allows for normal flow fluctu-

ations that occur in actual operations and for process control requirements.

6. Determine the column diameter $D_c = 12(4A_c/\pi)^{0.5}$.

Turndown and Minimum Wetting Flow

In general, the turndown of a packed tower is limited to the turndown of the liquid distributor, which is its ability to reduce liquid load and still maintain a homogeneous distribution. Most standard liquid distributors can operate efficiently at 50% of its design liquid load; turndown as low as 25% can be achieved.

To operate efficiently as mass-transfer devices, packing should be homogeneously wetted to assure use of the total surface. Minimum recommended values of liquid irrigation depend on the packing material and surface wettability, as follows:

Random packing

Ceramic	0.2 gallons min ⁻¹ ft ⁻²
Surface-treated or rusted metals	0.5 gallons min ⁻¹ ft ⁻²
Glass, glassed ceramic and stainless steel	1.0 gallons min ⁻¹ ft ⁻²

Structure packings

Surface-treated metals	0.2 gallons min ⁻¹ ft ⁻²
Plain surface metals	0.5 gallons min ⁻¹ ft ⁻²

especially for high-purity separations, only gravity distributions are used. **Table 6** illustrates the main type of distributors and the main factors to be considered for selection:

Type of Liquid Distributors

Liquid distributors can be gravity or pressure fed depending on how the liquid is introduced to the distributor. Pressure distributors are limited to heat transfer and some simple mass-transfer operations, mainly in stripping or absorption. For distillation,

Table 5 Relative capacity of packing and trays^a

^aTray capacity based on the column full cross-sectional area, without discounting any area for downcomers (which implies high-capacity trays). For conventional trays the ratio of packing capacity/tray capacity will be higher. Tray capacity taken from the generalized correlation of tray flooding proposed by Fair JR and Matthews RL (*Petroleum Refiner* 37(4): 153). The packing capacity taken from the generalized correlations presented by RF Striegler Jr and Figure 6).

- *Pipe orifice headers (POH)* (**Figure 8**) consist of a pipe ladder arrangement with calibrated orifices drilled in the pipe laterals in a uniform layout. POH can be pressure or gravity fed.
- *Pan distributors (PAN)* (**Figure 9**) consist of a flat horizontal plate (tray) with uniformly spaced calibrated orifices that allow the passage of liquid to the packing below. Round or rectangular risers (chimneys), located within the orifice pattern, distribute the vapour to the packing above. The riser layout should be uniform and should not interfere with the uniformity of the orifice layout. PAN distributors are always gravity fed.
- *Narrow trough distributors (NTD)* (**Figure 10A and 10B**). This distributor is composed of a series of narrow (3–4 inches) parallel troughs fed by one or more larger troughs (parting boxes) oriented at 90° from the narrow troughs. The narrow troughs distribute the liquid to the packing below, through calibrated orifices drilled at the bottom or at the wall. NTD are always fed by gravity.
- *Spray nozzle header (SNH)* (**Figure 11**). They are similar to POH but spray nozzles are used instead of orifices. The density of nozzles in the SNH is lower than the density of orifices in the POH. The SNH relies on the liquid cone leaving the nozzle for

further spreading. This results in either an overlap or a gap of the cone projection over the packed bed, and deteriorates the uniformity of the distribution. SNHs can handle very large liquid rates and are very efficient for heat transfer.

Liquid Mixing, Redistribution and Maximum Bed Height

Initial liquid distribution is essential to achieve good packed tower efficiency. Hoek suggested that at a given flow rate, each packing has its natural distribution determined by its radial spreading coefficient. Although this effect does spread the initial liquid distribution, this effect is not sufficient to correct poor initial distribution. Radial concentration gradients already established at the top of the bed cannot be compensated by additional packing. The result is permanent efficiency loss.

Figure 8 POH distributor. (Courtesy of Norton Chemical Process Products Corp.)

In general, if a good distribution is established at the top of the bed, the packing will develop its natural distribution and maintain it for bed depths of 10 NTS or more. Columns requiring more than 10 NTS per section should be subdivided into several packing beds to maintain coefficient HETP values. Liquid redistribution, and often mixing, are required between these bed sections.

Distributor Design Parameters

Distributor Liquid Level and Hole Diameter

The basic distributor design equation relates the total orifice open area, the liquid head and the volumetric flow:

$$Q = C_o n a_0 (h - h_d)^{0.5} \quad [12]$$

Figure 9 PAN distributor.

Figure 10 NTD distributor: (A) Photo courtesy of Norton Chemical Process Products Corp. (B) Photo courtesy of Koch–Glitsch Inc.

where Q is the volumetric flow rate, C_o the orifice flow coefficient, n the number of orifices, a_o the open area of one orifice, h the liquid head over the orifice, and h_d the vapour-pressure drop across the distributor given in head of liquid. The value of C_o varies between 0.5 to 0.8 and is near 0.6 for most commercial distributors. Using this value, eqn [12] becomes:

$$Q = 4.0nd^2(h - h_d)^{0.5}$$

and:

$$n = 0.25Q/d^2(h - h_d)^{0.5} \quad [13]$$

The minimum recommended orifice diameter, to prevent plugging, is 3/8 inch for carbon steel and 1/8 inch for stainless steel. The minimum recommended liquid level at minimum flow is 2 inches. If a 50% turndown is specified, the required liquid level at normal liquid load becomes 8 inches.

Figure 11 SNH distributor. (Courtesy of Norton Chemical Process Products Corp.)

Uniformity of the Drip Point Layout

Density of liquid drip points is not enough to assure a good distributor quality. The distribution must be homogeneous; the same amount of liquid should irrigate the packing at any fraction of the tower cross-sectional area. Areas near the tower wall should receive the same amount of liquid as areas near the centre.

Other Considerations

A number of factors need to be considered when selecting and designing packing and distributors.

Ratio Tower to Packing Size

The minimum recommended ratio of the tower diameter to the packing size is 8. In the case of structured packings, this ratio applies to the ratio of the tower diameter to the crimp size.

Fouling

Some solids are usually present even in 'clean systems' because of corrosion products, especially after maintenance shutdowns, when rust and debris can remain in the tower. The tower shell metallurgy should be adequate to prevent formation of scale or corrosion products that can plug distributors. Distributors with small orifices should be protected with filters in all liquid lines entering the tower. In other cases, solids are expected to be present because of the process itself. In these cases the distributor should be designed to handle the solids. A NTD distributor with V-notches for liquid overflow is adequate to handle

some slurries. SNHs can also handle slurries but their application is limited to heat transfer.

Vapour Distribution Requirements

Vapours entering the tower have a kinetic energy proportional to their velocity, which is converted into pressure as the vapour turns to start flowing upward in the tower. The resulting radial pressure profile is not uniform; areas of higher pressure would allow higher vapour up-flow. This is especially critical for low-pressure drop packings such as structured packings. Vapour radial velocity profiles are corrected by pressure drop and by diffusion devices. The following is the recommended practice for vapour distribution:

- Low vapour inlet velocity (velocity head below 0.5 inches of water): no inlet distributor required, provide as minimum $1\frac{1}{2}$ column diameters, or 36 inches between the top of the vapour inlet nozzle and the bottom of the bed.
- Intermediate vapour inlet velocity (velocity head between 0.5 and 1.5 inches of water): provide an inlet vapour diffuser directing vapour flow down the tower. This type of device can be a horizontal pipe with the bottom half cut as shown at the bottom of the column in **Figure 2**. Vertical baffles can be provided for better vapour distribution. The purpose of these baffles is to stop the horizontal velocity component of the vapour.
- High vapour velocity (velocity heads above 1.5 inches of water): provide an inlet vapour diffuser, as described above, plus a small riser chimney tray with a pressure drop of a minimum of 2 inches of water. The pressure drop can be created by orifices at the bottom of the risers. A vapour distributor, as shown in **Figure 12** is a good alternative to the vapour diffuser in critical systems.

Distributor Testing

Water test of assembled distributors at the manufacturer's workshop is always a good practice for all high-efficiency distributors. The test should determine liquid rate gradients under the distributor, liquid level in the distributor itself at design and

turndown liquid rate, liquid level gradient in the trough and uniformity of the drip point layout. These parameters should be compared to the distributor design parameters and adjustments made to the distributor if necessary. **Figure 13** shows a distributor testing facility.

Packing Performance in Distillation

Factors to Consider in Determining the Column Design HETP

The height equivalent to a theoretical plate (HETP) is determined by the following main three factors:

Intrinsic geometric shape and size of the packing

This factor determines the surface per unit of volume, and the packing capacity of establishing effective vapour liquid interfacial surface. It is a well-known fact that, for any packing, the smaller its particle size, the larger its surface : volume ratio, and the lower the HETP value. All the other factors being equal, numerous available data tend to indicate that the expected reference packing $HETP_o$ may be correlated as follows:

$$HETP_o = K_p / F_p^f \quad [14]$$

where F_p is the packing factor. The constants K_p and f for different types of commercial packing are correlated as in **Table 7** for a reference system.

Figure 12 Vapour distributor. (Courtesy of Sulzer Chemtech.)

Figure 13 Distributor testing facilities. (Photo courtesy of Koch-Glitsch Inc.)

Table 7 HETP correlation factors for a reference system, regressed by the authors for eqn [14]

Packing	Constant K_p	Exponent f
<i>Structured packings</i>

Pall Rings	250	0.69
Average above random packings	110	0.50

properties:

$$\text{HETP} = \text{HETP}_o (\mu\alpha/S_g\delta)^n / (\mu\alpha/S_g\delta)_o^n \quad [15]$$

when the n exponent best fit is between 0.15 and 0.21. Replacing HETP_o from eqn [14] into eqn [15], and using the reference system we obtain:

$$\text{HETP} = (2.0K_p/F_p^f) (\mu\alpha/S_g\delta)^{0.2} \quad [16]$$

In addition, theoretical considerations suggest that the HETP is related to $\lambda = m/(L/V)$, the ratio of the slopes of the equilibrium line and operating line, by the correlation:

$$\text{HETP} = \lambda \ln(\lambda)/(\lambda - 1) \text{HTU}$$

System properties Numerous investigations have tried to correlate experimental HETP data with the distillation system fluid physical properties. The best and most consistent correlations tend to confirm that the HETP is proportional to reference HETP_o and a factor proportional to the system physical

where HTU is the height of a transfer unit. Then:

$$\text{HETP} = (2.0K_p/F_p^f) (\mu\alpha/S_g\delta)^{0.2} f(\lambda) \quad [17]$$

Packing loading Figure 14 shows the pilot plant performance of Sulzer/Nutter ring No. 2.5 in

**Figure 14** HETP vs. loads. (Courtesy of Sulzer Chemtech.)

isobutane-n-butane separation. Note that although only the vapour rate appears in the abscissa, actually both the vapour and the liquid rates increase in the same proportion since the chart was developed at total reflux. All packings present similar curves in small size experimental columns. The initial HETP is high (low efficiency) owing to the low loads that result in liquid maldistribution, poor packing wetting and little interaction between the vapour and the liquid (this left section of the curve is not shown in Figure 14). Nevertheless, the HETP continuously decreases as the loads increase. At a point, corresponding to the loading point of the packing, the HETP becomes constant over a range of loads. This range represents the operating range of the packing. As the loads continue to increase, the HETP shows a dip corresponding to high interaction between the fluids, followed by a rapid increase in the HETP caused by recirculation of liquid within the bed. This corresponds to the initial flooding of the bed.

Maldistribution

Liquid maldistribution has a very large effect on column distillation performance. Liquid maldistribution is originated by uneven liquid flow from the distributor to the top section of the packing. Some degree of maldistribution cannot be avoided and it is related to the following factors.

Drip points density (total drip points/column cross-section area) In principle, a smaller number of drip points equates to a higher initial maldistribution. This could be solved by constructing distributors with a high number of drip points. However, there are physical and mechanical limits that make it difficult to build distributors with more than 20 drip points ft^{-2} . It has also been demonstrated that if the distributor deck is not levelled, the resulting maldistribution effect may increase as the number of drip points is increased above an optimal number. The optimal number of drip points is related to the liquid irrigation flow as follows (Figure 15):

Liquid irrigation $\text{g} \cdot \text{m}^{-1} \cdot \text{ft}^{-2}$	0.25	0.5	1.0	2.0	4.0
Optimum number drip points per square foot	5	8	13	21	32

Furthermore, the drip points themselves may create additional maldistribution if they are not evenly distributed across the entire column cross-sectional area. Poor construction making holes of variable diameters or unlevelled installation of the distributor will also

Figure 15 Effect of number of drip points and liquid irrigation rate on maldistribution. (Permission from Chemical Engineering Progress.)

induce additional maldistribution. Operational problems such as plugging of the distributor deck areas will cause large sectors to be dry, thus producing a macroscopic or sectorial maldistribution.

Maldistribution and spreading factor Initial maldistribution produces a condition of uneven liquid/vapour flow ratio across the column cross-sectional area. Some areas or spots are underirrigated and some are overirrigated. The column packing does spread the liquid resulting in some correction or attenuation of the initial maldistribution. The overall weighted maldistribution is attenuated better in small diameter columns than in larger columns. This is determined by the nondimensional number (Z_b/CD_c^2) , where Z_b is the bed height in feet, D_c the column diameter in inches, and C is the spreading factor in $\text{ft} \cdot \text{in}^{-2}$ units (see Figure 16). The spreading factor is related to the packing particle size and the liquid irrigation.

The lost column efficiency is proportional to the liquid maldistribution, and this effect is amplified by the number of theoretical stages required to achieve the separation. Figure 17 presents a useful correlation for the calculation of the column efficiency in packed distillation columns.

Liquid distributor quality The liquid distributor intrinsic maldistribution, M_d (related to its design and manufacture) should be measured at the factory by a water test measuring the liquid flow under each subsection of the column cross-section. The smaller and more numerous the test area subdivisions, the more precise will be the maldistribution

Figure 16 M vs. Z_b/CD_c^2 . (Permission from Chemical Engineering Progress.)

measurement. The mathematical expression of the maldistribution is:

$$M_d = 100[\Sigma((L_i/L_{av} - 1)^2)/n]^{0.5} \quad [18]$$

for each point area subdivision from $i = 1$ to $i = n$. The following is the correlation between distributor quality and its maldistribution:

$$Q_d (\%) = 100/[1 + (M_d/100)^2] \quad [19]$$

If the distributor quality is 90%, the actual measured maldistribution should not exceed 33%. A 95% quality implied a maximum measured maldistribution of 23%.

Total maldistribution Additional maldistribution can originate from operational factors related to levelness and obstructions. The total initial maldistribution, M_o , can be calculated by:

$$M_o = (\Sigma M^2)^{0.5} \quad [20]$$

Assuming a maximum operational maldistribution $M_{op} = 15\%$, and using a 90% distributor quality ($M_d = 33\%$), the total effective operating maldistribution at the top of the packing is $M_o = (33^2 + 15^2)^{0.5} = 36.2$.

The effective bed attenuated maldistribution is calculated by the following equation:

$$M_{bz} = M_o/[1 + 0.16M_o(Z/CD_c^2)] \quad [21]$$

With this M_{bz} value, the bed efficiency E_z may be obtained from Figure 17. The calculated bed efficiency should be used to correct the packing HETP and obtain the bed operating HETP_{op}:

$$\text{HETP}_{op} = \text{HETP } E_z/100 \quad [22]$$

$$\text{HETP}_{op} = [(2.0 K_p/F_p^f)(\mu\alpha/S_g\delta)^{0.2} f(\lambda)]E_z/100. \quad [23]$$

Figure 17 Efficiency vs. NTS.

The bed effective number of theoretical stages can be calculated by:

$$\text{NTS} = Z/\text{HETP}_{\text{op}}. \quad [24]$$

For a column requiring more than 10 NTS, it is in general advantageous to subdivide the packing in two or more beds and limit the NTS per bed to around 10. The lower the NTS per bed, the higher the resulting bed efficiency. The limiting factor of subdividing the column into a large number of redistributed beds, is the extra column height (or the effective packed height loss for column revamps) necessary to accommodate each redistributor, and the resulting increased cost. For new columns, the optimal number of beds is the one that results in the required performance at minimum cost, for revamps, it is often the one that results in the maximum available overall NTS. The best choice in each case is determined by an optimization.

Future Developments

With the ability to accurately design and predict the performance of packings in distillation, it is expected that the use of packings in distillation will become better accepted, not only for plant revamps but also for grass roots applications. The design and evaluation of liquid distributors needs to be better understood by users and equipment manufacturers; standard methods for distributor quality rating should be implemented based on the basic concepts presented in this contribution. Readers interested in further exploring the column design methods outlined in this article may download a free demo of BDSIM at url <http://www.geocities.com/~combusem/BDSIM.HTM>

Pilot Plant Batch Distillation

**M. A. P. de Carvalho and
W. R. Curtis**, The Pennsylvania State University,
PA, USA

Introduction

Laboratory distillation encompasses an operating range from millilitres in bench-top devices to pilot units with the capacity for producing several hundred kilograms of product per day. While the design of bench-top assemblies is generally geared towards the achievement of a specified purity grade of the desired product, quantitative predictions are not usually feasible for such equipment and their construction relies a great deal on ingenuity and craftsmanship. For dedicated applications, glassware companies offer off-the-shelf equipment. This article will therefore focus on the pilot-scale units, where the analytical principles of mass and heat transfer can be applied to the operation, design and optimization of the equipment.

The section on theory presents analytical descriptions of batch distillation for three different approaches in order of decreasing complexity. It starts with a comprehensive model for a nonadiabatic, non-zero hold-up, nonconstant molar overflow, nonideal multicomponent column. The second model presented neglects stage hold-ups and assumes adiabatic stages and constant molar overflows to arrive at a set of equations describing the transient behaviour of the equipment, which can be solved for a binary system using a simple spreadsheet. If constant relative volatility and operation at minimum reflux are further

assumed, the derivation of a third model is possible, where the transient states within the equipment are given by direct analytical expressions.

The design of a batch column can be a challenging task because batch distillation presents unique considerations that are not addressed in most of the available literature, which is concerned with continuous operation. The section on design is a collection of advice and criteria for the design of batch columns. Specific information is given about equipment for batch distillation and accompanying instrumentation and safety circuitry. Details are drawn from a pilot-scale column that is installed in Penn State University's Department of Chemical Engineering. The section on column operation extends the scope of the two preceding sections by providing information on establishing operating strategies and operating protocols for batch runs. Much of this information is based on hands-on experience acquired with the column described in the subsection on equipment.

The last section is a synopsis of numerical techniques that have been developed in recent years to facilitate the optimization of the operation and design of batch columns. Inherent difficulties associated with the implementation of these numerical techniques into computer codes prevents their widespread use in equipment operation and design. However, it is likely that these techniques will be integrated into commercial simulators in the near future and be readily available to users with little knowledge of programming. The aim here is to introduce the reader to the topic, rather than to offer extensive coverage,

providing references for those interested in further reading.

Theory

The theory of batch distillation permits design, operation and optimization calculations by integrating the concepts of thermodynamic equilibrium, mass and heat transfer, energy and material balances to solve the problem of predicting the compositions and flow rates of process streams. The traditional approach to the development of governing equations is to model the equipment as a stack of equilibrium stages. Departures from ideality are taken into account by introducing the concept of stage efficiencies. Modelling in terms of equilibrium stages is convenient because of the availability of extensive equilibrium data for multicomponent systems and the associated predictive thermodynamic models. Packed columns, which do not possess physical mass transfer stages, can be translated into this technical framework by the use of the transfer unit concept (see, for example, McCabe *et al.*, 1993).

Relinquishing or including levels of complexity and interdependence in the fundamental equation and process variables will result in more or less rigorous treatments, with gains in accuracy usually being accompanied by substantial drawbacks in complexity and computational difficulty. Hereunder, three different sets of model equations are presented in decreasing levels of complexity. A rigorous approach to the problem involves the solution of a set of time-dependent differential and algebraic equations for the material and heat balances and for the equilibrium relations. Batch columns are usually constructed so that there is only one section, either above or below the feed stage. The typical column design depicted in **Figure 1** represents the rectifying section. From this simplification it is possible to write the following equations to define the problem completely in each stage except the top stage and the feed drum (reboiler).

Total material balance

$$\frac{dh_{\text{tot},i}^L}{dt} = L_{i-1} + V_{i+1} - L_i - V_i \quad [1]$$

Component material balances

$$h_{\text{tot},i}^L \frac{dx_{i,j}}{dt} = L_{i-1}x_{i-1,j} + V_{i+1}y_{i+1,j} - L_ix_{i,j} - V_iy_{i,j} \quad [2]$$

$i = 1, N_{\text{stage}}, j = 1, NC$

Figure 1 Batch distillation column schematic for a rectifying configuration.

Energy balance

$$\left(h_{\text{tot},i}^L \sum_{x=1}^{NC} x_{i,j} \frac{dH_{i,j}^L}{dT} \right) \frac{dT}{dt} = L_{i-1}x_{i-1,j}H_{i-1,j}^L + V_{i+1}y_{i+1,j}H_{i+1,j}^V - L_ix_{i,j}H_{i,j}^L - V_iy_{i,j}H_{i,j}^V + Q_i \quad [3]$$

$i = 1, N_{\text{stage}}, j = 1, NC$

Vapour liquid equilibrium relation

$$y_{i,j} = f(x_{i,j}) \quad [4]$$

Summation of liquid mole fractions

$$\sum_{j=1}^{NC} x_{i,j} = 1 \quad [5]$$

Summation of vapour mole fractions

$$\sum_{j=1}^{NC} y_{i,j} = 1 \quad [6]$$

Liquid total hold-up constraint

$$h_{\text{tot},i}^L \left(\sum_{j=1}^{\text{NC}} x_{i,j} v_j \right) = \text{Vol} \quad [7]$$

Eqns [1]–[7] ignore the tray hydraulic behaviour and assume identical compositions for the liquid hold-up within a stage and the liquid outflow out of the stage. Other major features and assumptions of the model are nonadiabatic stages, negligible vapour hold-up and constant volumetric liquid hold-up. The assumptions concerning the hold-up are very reasonable and the equations can be readily translated to real stages by the introduction of Murphree tray efficiencies as correction factors for either the liquid or the vapour compositions.

For the top stage, the liquid inflow is related to the distillate outflow by the reflux ratio, and for the feed drum, the depletion of material should be taken into account. There is also no liquid outflow for the reboiler, thereby decreasing the number of necessary equations by one (eqn [7]). The following equations are the modified set for the situation in the top stage and reboiler.

Top stage: total material balance

$$\frac{dh_{\text{tot},1}^L}{dt} = DR_D + V_2 - L_1 - V_1 \quad [8]$$

Component material balances

$$h_{\text{tot},1}^L \frac{dx_{1,j}}{dt} = DR_D x_{D,j} + V_2 y_{2,j} - L_1 x_{1,j} - V_1 y_{1,j} \quad [9]$$

Energy balance

$$\begin{aligned} & \left(h_{\text{tot},1}^L \sum_{x=1}^{\text{NC}} x_{1,j} H_{1,j}^L \frac{dH_{1,j}^L}{dT} \right) \frac{dT}{dt} \\ &= DR_D x_{D,j} H_{D,j}^L + V_2 y_{2,j} H_{2,j}^V - L_1 x_{1,j} H_{1,j}^L \\ & \quad - V_1 y_{1,j} H_{1,j}^V + Q_1 \end{aligned} \quad [10]$$

For the feed drum (reboiler) the following equations are modified.

Total material balance

$$\frac{dh_{\text{tot},R}^L}{dt} = L_{N \text{ stage}} - V_R \quad [11]$$

Component material balances

$$h_{\text{tot},R}^L \frac{dx_{R,j}}{dt} = L_{N \text{ stage}} x_{N \text{ stage},j} - V_R y_{R,j} \quad [12]$$

Energy balance

$$\begin{aligned} & \left(h_{\text{tot},R}^L \sum_{x=1}^{\text{NC}} x_{R,j} H_{R,j}^L \frac{dH_{R,j}^L}{dT} \right) \frac{dT}{dt} \\ &= L_{N \text{ stage}} x_{N \text{ stage},j} H_{N \text{ stage},j}^L - V_R y_{R,j} H_{R,j}^V + Q_R \end{aligned} \quad [13]$$

The set of equations written for all the stages forms a system of nonlinear differential algebraic equations, with initial conditions given by the original charge in the feed drum, tray hold-ups and tray composition profiles and internal flow rates. The vector of initial conditions represents a pseudo steady-state solution for an initial feed whose composition is equal to the vapour in equilibrium with the liquid charge of the feed vessel. The transient behaviour is obtained by the simultaneous solution of eqns [1]–[13], which requires linearization and a combination of matrix inversion and integration techniques.

Despite the large range of computational complexity, simulations of batch distillation show that, in most cases, short-cut and rigorous models agree very well. A distinct advantage of the simplified models is they can be implemented in a spreadsheet. In these models the stage hold-up is considered negligible, except for the feed drum (reboiler) where the following equations hold for the total and volatile component material balances in a column operating at constant distillate composition and variable reflux.

Total cumulative material balance

$$\bar{D} = \bar{V} - \bar{L} \quad [14]$$

$$\begin{aligned} dW &= -d\bar{D} = \left(1 - \frac{\bar{L}}{\bar{V}} \right) d\bar{V} = \left(1 - \frac{R}{R+1} \right) d\bar{V} \\ &= (1-S) d\bar{V} \end{aligned} \quad [15]$$

Cumulative component balance

$$W_i x_{wi} = W x_w + (W_i - W) x_D \quad [16]$$

By differentiating and rearranging one gets:

$$W = \frac{W_i (x_{wi} - x_D)}{(x_w - x_D)} \quad [17]$$

$$-dW = \frac{W_i (x_D - x_{wi}) dx_w}{(x_D - x_w)^2} = d\bar{D} \quad [18]$$

If eqn [18] is substituted in [15] one gets:

$$(1 - S) d\bar{V} = \frac{W_i(x_D - x_{wi}) dx_w}{(x_D - x_w)^2} \quad [19]$$

The total amount of vapour produced will then be:

$$\bar{V} = \int_{x_{wi}}^{x_{wf}} \left[\frac{W_i(x_D - x_{wi})}{(1 - S)} \right] \frac{dx_w}{(x_D - x_w)^2} \quad [20]$$

Since the cumulative vapour produced is $\bar{V} = \theta V$, the time θ necessary for a run is calculated from the above equation as:

$$\theta = \int_{x_{wi}}^{x_{wf}} \left[\frac{W_i(x_D - x_{wi})}{V} \right] \frac{dx_w}{(1 - S)(x_D - x_w)^2} \quad [21]$$

The total amount of distillate produced can be found by integration of eqn [18]:

$$\int_0^{\bar{D}_f} d\bar{D} = \int_{x_{wi}}^{x_{wf}} \frac{W_i(x_D - x_{wi}) dx_w}{(x_D - x_w)^2} \quad [22]$$

Finally, rearrangement of eqn [16] yields:

$$W_i x_{wi} - (W_i - W)x_D = W x_w \quad [23]$$

$$W_i x_{wi} - \bar{D} x_D = W x_w \quad [24]$$

The above can be differentiated to give the following result:

$$d(W_i x_{wi} - \bar{D} x_D) = d(W x_w) \quad [25]$$

$$- d(\bar{D} x_D) = d(W x_w) \quad [26]$$

$$- x_D d\bar{D} = x_w dW + W dx_w \quad [27]$$

The remaining amount of charge in the still is then calculated by combining the above equation with the total differential balance $dW = -d\bar{D}$ and subsequently integrating the resultant expression:

$$\frac{dW}{W} = \frac{dx_w}{x_D - x_w} \quad [28]$$

$$\ln \frac{W_f}{W_i} = \int_{x_{wi}}^{x_{wf}} \frac{dx_w}{x_D - x_w} \quad [29]$$

Eqns [20]–[22] provide an efficient way of calculating the total amounts of vapour and distillate produced and the time necessary for the separation without having to solve the system of equations comprised by eqns [1]–[13]. This calculation provides an economic benchmark since it defines the optimum time for a run, based on the recovered product value and the operating costs. As the run time increases, the cumulative revenues given by the total amount of recovered product multiplied by its value will first increase but then approach an asymptotic value. The decreased economic benefit results either because the amount of distillate decreases (as in the case of constant composition distillate) or because the product stream becomes progressively less pure (as in the case of constant reflux ratio operation). The operating costs on the other hand increase steadily with time and the profit function, which combines these two costs, undergoes a maximum, after which the profit will decrease, as illustrated by **Figure 2**.

An analytical solution can be found for a limiting case which assumes an infinite number of stages (corresponding to minimum reflux) and constant relative volatility. At minimum reflux the operating line ends at a pinch zone and x_w is located in the equilibrium

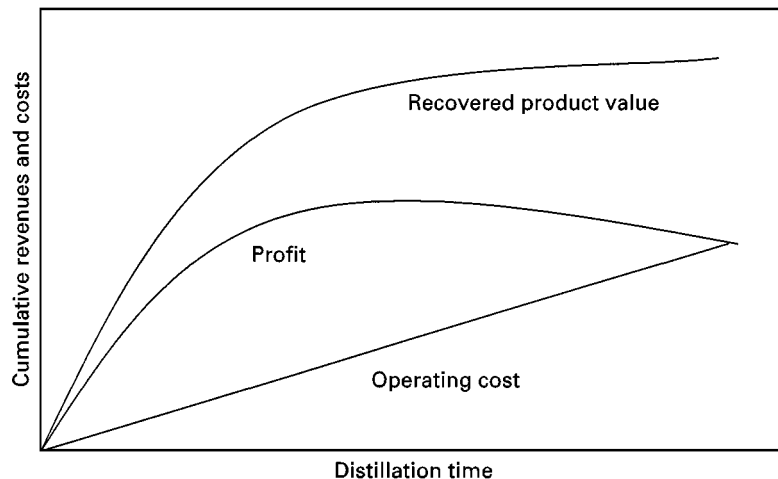

Figure 2 Optimum profit profile: operating costs versus length of time. Recovered product increases rapidly at first but then levels off.

line. The slope of the operating line is then given by:

$$S = \frac{d\bar{L}}{d\bar{V}} = \frac{x_D - y_w}{x_D - x_w} = \frac{R}{R + 1} \quad [30]$$

Under the constraint of constant relative volatility the equilibrium relation becomes:

$$y_w = \frac{\alpha x_w}{1 - x_w(\alpha + 1)} \quad [31]$$

If one takes advantage of eqns [30] and [31], analytical forms for the cumulative distillate production and remaining charge left in the feed still can be derived for the cases of either constant reflux ratio or constant distillate composition operation.

For constant reflux ratio, eqn [15] can be integrated to the expression for the total vapour requirement:

$$\bar{V} = (R + 1)\bar{D} = (R + 1)(W_i - W_f) \quad [32]$$

Combination of eqns [15], [30] and [31] yields the functional dependence of distillate composition, x_D on recycle ratio, R , composition of the remaining feed, x_w in the reboiler and relative volatility, α :

$$x_D = \frac{(R + 1)\alpha x_w - R x_w - R x_w^2(\alpha - 1)}{1 + x_w(\alpha - 1)} \quad [33]$$

Substitution of eqn [33] into the general mass balance expression, eqn [29] and subsequent integration produces an analytical form for the mass balance given by:

$$\ln \frac{W_f}{W_i} = \frac{1}{(R + 1)(\alpha - 1)} \ln \left[\left(\frac{1 - x_{wi}}{1 - x_{wf}} \right) \left(\frac{x_{wf}}{x_{wi}} \right) \right] + \left(\frac{1}{R + 1} \right) \ln \left(\frac{1 - x_{wf}}{1 - x_{wi}} \right) \quad [34]$$

If the column is operated at constant distillate composition, direct integration of eqn [29] produces the expression for the mass balance:

$$\frac{W_f}{W_i} = \left(\frac{x_D - x_{wi}}{x_D - x_{wf}} \right) \quad [35]$$

The integration of eqn [20], however, requires the development of an expression for the time-dependent operating line, which is accomplished by substitution

of eqn [31] into [30] to yield:

$$\frac{d\bar{L}}{d\bar{V}} = \frac{x_D + x_D x_w (\alpha - 1) - \alpha x_w}{(x_D - x_w) [1 + x_w(\alpha - 1)]} \quad [36]$$

Substitution of [36] into the general expression for the vapour requirement (eqn [20]) and integration leads to the vapour requirement equation when the column is operated at constant distillate composition and variable reflux:

$$\bar{V} = \frac{W_i(x_D - x_{wi})}{(1 - x_D)(x_D)(\alpha - 1)} \times \left\{ (1 - x_D) \ln \left[\left(\frac{x_D - x_{wf}}{x_D - x_{wi}} \right) + \left(\frac{x_{wi}}{x_{wf}} \right) \right] + x_D \alpha \ln \left[\left(\frac{x_D - x_{wf}}{x_D - x_{wi}} \right) \left(\frac{1 - x_{wi}}{1 - x_{wf}} \right) \right] \right\} \quad [37]$$

Eqns [34] and [37] were developed by Bauerle and Sandall, assuming the ideal pinched columns operating at minimum reflux. None the less, their application to real columns yields good approximated results if the equipment operates in a near-pinched zone at the bottom. This is often the case for columns with five or more theoretical stages.

Design

The operation of a batch distillation column, even pilot-scale equipment, is often as technically involved as operation of an industrial-scale column, and the same amount of care in start-up and safety procedures should be taken. Whether designing a new column or revamping an existing one, the necessary safety and physical properties data such as flash and ignition points, flammability and toxicity must be compiled for each component in the mixture. Predictive equations or experimental values for the vapour pressures of all components and binary equilibrium data should be compiled together with parameters of equations of state or activity coefficient models whenever available. Other physical properties to be included are liquid and vapour heat capacities, heats of vaporization and viscosities.

Once the physical property data bank has been put together, preliminary design calculations can be performed. For a multicomponent distillation column a light-key and a heavy-key component should be chosen in order to reduce the preliminary design to a pseudo-binary system. At this point it is possible to use graphical methods like McCabe-Thiele or even something more involved like Ponchon-Savarit to

carry out a case study to find out the system response in terms of required number of theoretical stages for a specified purity at different reflux ratios. To accomplish this, the optimization techniques described later can be useful, but since they are also hard to implement. The alternative approach of using a simplified calculation method such as presented in the section on column operation might be more desirable. This initial set (reflux ratio — number of theoretical stages) will permit the preliminary design.

Depending on the intended purpose of the laboratory-scale column, these initial calculations are likely to be sufficient for specifying the details of column design. Reboiler and condenser heat loads permit sizing of steam and condensation coils. Environmental concerns have introduced complexities in design which were not previously an issue for pilot-scale distillation. Current regulations at our site require condensate return to steam generation facilities to recover waste heat. Even a moderate condenser heat load can require prohibitively large quantities of cold tap water and the condenser heat load for even a small distillation column will typically be substantially larger than can be handled by laboratory-scale recirculated chillers. Much of the final decisions on absolute sizing will be dependent upon available facilities and the anticipated intensity of column use. It is important to get to a reasonably accurate preliminary design early in the design process, so that such practical constraints can be considered.

In many situations, a laboratory-scale distillation column will be used for multiple separations, or as a testing ground for additional full-scale design data. Under these circumstances, design for flexibility is a primary concern. Instead of focusing on detailed physical property information, the data collection should focus on obtaining ranges of anticipated physical properties as well as ranges in batch size. The actual design should then reflect the appropriate bounds of properties and separations that may be encountered. It should be kept in mind that there is a practical minimum volume that can be handled, due to tray hold-up, while larger volumes can be handled with multiple batches. Undersizing either reboiler or condenser heat transfer capacity may render the column useless for a specific separation.

In most batch distillation operations, the lighter component is the desired product and the actual column is the rectifying section of a continuous tower. The preceding discussion in this section as well as in the next section implicitly assume this situation. Nevertheless, there might arise design situations where the economical interest lies in the heavier compounds. In more complex operations the designer might even be faced with the task of devising a separ-

ation sequence involving two or more columns. For the case where it is desired to recover the heavy component, the calculations for the number of stages should be performed as a stripping column instead.

Since the principles and computational basis of distillation are quite advanced, additional assumptions allow the derivation of simple expressions for the distillate composition and flow rate and the amount of material left in the feed drum. These assumptions render the evaluation of columns with recycle amenable to straightforward solutions.

The remainder of this section includes a description of a versatile laboratory distillation column and its instrumentation and safety systems.

Equipment

Batch distillation equipment can be custom-made to meet particular design specifications or be directly purchased by catalogue selection if no stringent construction features or materials are required. Ordering can be greatly facilitated by a previous search of the manufacturers or suppliers in the worldwide web. Equipment intended to be used for research or educational purposes should be made of glass whenever possible, given the easy observation of the internal flow regimes and their change with the internal flow rates. An existing batch glass column is described here as an example.

Figure 3 shows a distillation column which has a simple conceptual design but is versatile enough to be used for research or teaching applications. The column is atmospheric and functions as the rectifying section of a regular distillation column. The feed drum doubles as a kettle vessel where the feed is vaporized by a coil heater having steam as the heating medium. Instrumentation is reduced to the essentials: the distillate and reflux flow rates are controlled by varying the rotation speed of the distillate and reflux pumps, and the feed flow rate can be controlled by varying the steam pressure in the coil. The safety system consists of a relay actuated by the occurrence of any of the failure conditions in the column, which are pressurization within the equipment, zero flow of condenser cooling water or loss of power to the ventilation system. When any of these conditions occurs, steam admission to the feed drum is switched off.

The pumps are actuated in the remote mode by a driver board that receives signals in the range between 4 and 20 mA from an analog output board installed in a PC. The connection between the pump driver board and the analog output board consists of a screw terminal connector. The variation of the output signal to the pumps is accomplished via

Figure 3 Rectifying batch distillation column. The abbreviations are as follows: A/D board = analog to digital interface board, CW = cooling water, D. Pump = distillate pump, F. Pump = feed pump, FIC = flow indicator control, P. chiller = product chiller, P. Tank = product tank, PI = pressure indicator, PIC = pressure indicator control, R. Disk = rupture disk, S. Valve = safety valve and TI = temperature indicator.

a software utility provided with the board that emulates a control panel, where each of the instruments hooked to the board is assigned a channel number displayed in the panel screen. The user varies the pump flow rate by changing the output current at the computer screen. Manual local control of each pump is also provided in case of failure of the computer-interfaced control. The stepper motor of the steam valve for the feed drum steam coil is also interfaced in a comparable manner.

The column is also provided with thermocouples for each stage, including condenser and reboiler. The thermocouples are wired to a screw terminal connector, that provides the interface to an analog/digital I/O board installed in the PC. When there is a significant difference between the boiling points of the two components of a binary system, the stage temperature is an efficient and straightforward way of evaluating compositions. Under these circumstances, the real-time composition profile within the column can be updated to the computer screen. Sample ports for the liquid phase are installed in every stage, including the condenser and reboiler to corroborate thermal measurements under circumstances where thermal gradients are not sufficiently steep to provide accurate composition correlation. The composition analysis can be performed by a variety of methods. If there is a significant density difference between components being separated, composition can be deduced from a density-concentration curve. Density can be deter-

mined gravimetrically, or equipment is available for online density measurement. A particularly versatile online implementation of density measurement is in the condensate stream of an off-set condenser as described in more detail below. If one of the components is an organic acid, sample analysis can be carried out either by titration or by the measurement of any other property related to the dissociation state (such as pH), provided the metering apparatus is sufficiently accurate to discriminate stage-to-stage differences. For organic mixtures, other properties such as refractive index may also be used as analytical method.

The feed drum in the described pilot-scale column is a large glass bulb equipped with a steam heating coil to vaporize the feed. A pressure relief rupture disk provides a mechanical fail-safe against reboiler pressurization. Another pressure gauge is installed at the steam inlet to the coil. The steam outlet is provided with a trap to ensure the total condensation of the steam, and therefore the use of its latent heat. A useful energy balance is achieved by cooling the condensate as it is discharged to the drain. The heat load to the column can be crudely calculated by measuring the discharge flow rate and multiplying this value by the heat of vaporization of the steam at the inlet pressure.

The distillate is collected in a separate vessel whose volume equals approximately half that of the feed drum. The product collection vessel is fitted to permit

charging of material to the feed drum. The remaining material in the drum after a batch processing can be discharged by a valve in the bottom. The subsequent batch charge can also be combined with the remaining heavy ends of the previous operation.

The off-set condenser depicted in Figure 3 provides for direct measurement of condensate flow rate. This eliminates the need to calculate condensate from the condenser energy balance. This is particularly important for pilot-scale units where complete condensation may not be achieved at high boil-up rates. The condensed top vapours drip down and accumulate in the bottom part of the vessel, from which they are removed either to the distillate tank or back to the column as reflux. A match between the condensation rate and sum of product and liquid flow rate returned to the column can be assured by visual monitoring of the condenser liquid level or computer monitoring of the liquid head in the bottom of the condenser with a pressure transducer. The gas entrance to the condenser doubles as a liquid overflow in the event of excessive condensate accumulation.

Instrumentation and Safety Circuits

Although a batch distillation column can be run manually by an attentive and experienced technician, the dynamic nature of operation requires extensive instrumentation for all but the simplest mode of operation. To gain the flexibility necessary for the operation at constant distillate composition, flow rates of the reflux and distillate must be independently controlled. In small units devoted to research, flow control can be easily accomplished by varying the speed of a gear pump through a control panel displayed on a computer screen. The connection of the pump to the computer consists of a driver board wired to a screw terminal connector. The latter is attached to an analog output board. The output signal to the driver board can be varied based on the results of calculations performed by external application programs. If the top composition is to be kept constant, the update on the reflux rate can be calculated by a user routine with the aid of operating charts such as those described later. The value of the reflux rate translated to flow rates (typically current values) controls the distillate and reflux pumps. The product and reflux flow rates must be constrained to balance the rate of condensation. This is conveniently accomplished by monitoring the condenser level as an indicator of the difference between boil-up and distillate and product flow rates. The direct use of the heat load output to control the condenser level is not recommended due to the large dead-time between a change in the reboiler conditions and the resulting effect in the liquid

level. The result of the reflux calculation is stored in a data buffer from which it can be retrieved by another application and used to update the corresponding analog output channel.

Analog and digital I/O boards can also be installed to retrieve information such as cooling water temperature and flow rate, steam pressure, flow rate to the reboiler and the temperature profile of the column. The stage temperature is a direct indicator of stage composition; however, it is only useful as a control variable when the temperature variation between successive stages is significant. The greatest variation in temperature during the batch run will take place in the reboiler which is an excellent means of monitoring overall progress of the separation.

Variation of the heat load to the column can be actuated remotely by fitting the steam valve with a stepper motor. A variable heat load adds operation flexibility and can be used in conjunction with other strategies to maximize recovery and purity of a desired component at a lower energy cost. For example, the feed drum contains the highest fraction of the volatile component at the beginning of the process. Therefore, the column can be started up at a lower boil-up rate, which will be gradually increased to match the enrichment of the charge in the heavier component. Figure 3 shows typical column instrumentation, and data acquisition and control.

Three operating conditions are monitored constantly and may independently activate the safety system, stopping steam delivery to the reboiler by closing a steam safety valve that precedes the steam controller valve. These monitored conditions are the column pressure, cooling water flow and ventilation fans. The pressure transducers, flow transmitter and power to the fans are set up as a logic relay where loss of any one of the direct current voltages is sufficient to actuate the steam safety valve. It is important to choose the logic of these circuits such that electrical and mechanical failures will default to termination of the batch run. The safety system circuitry is depicted in Figure 4.

Column Operation

While dedicated laboratory-scale distillation can be used for solvent recovery, experimental laboratory-scale columns are used for collection of design data. The operational objective is usually to maximize the recovery of a component under the constraint of a desired purity level. The feature of the batch process which distinguishes it from the more familiar continuous counterpart is its inherently transient nature. The continuously changing feed composition must be

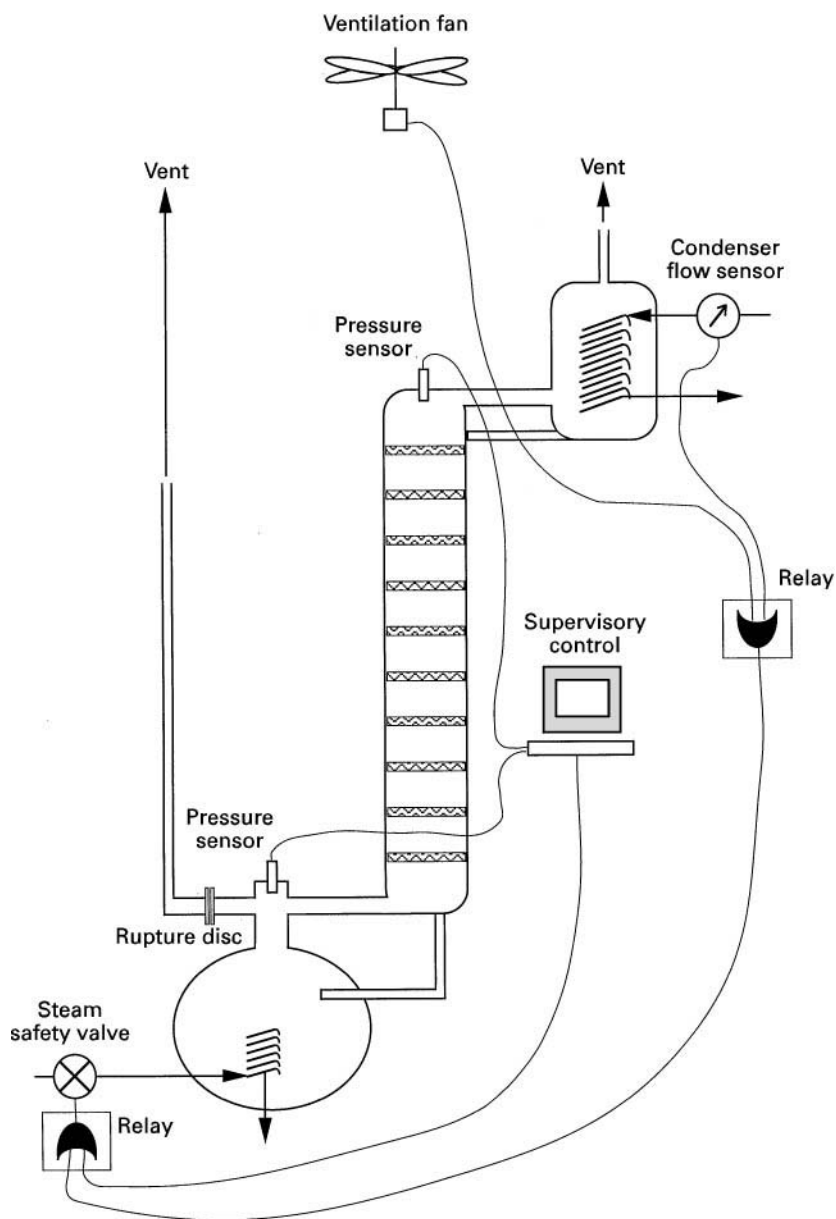

Figure 4 Safety system circuitry.

accounted for in the calculation theory. A variety of operation and completion criteria may be used depending on the process economics, equipment characteristics and product value. Several different basic operational modes are possible:

1. total reflux, with periodic dumping of the accumulated material from the condenser to the distillate tank;
2. constant reflux, with continuous variation of the instantaneous distillate composition, starting above and finishing below the desired product specification;
3. constant composition, with variable reflux ratio in order to keep the instantaneous distillate composition constant.

Operation strategies can take advantage of all three of these operational modes.

Initially the column is operated at total reflux with subsequent product collection at a purity higher than the final product specification. After this initial cut is withdrawn to the product tank, operation is switched to the constant composition mode and the equipment is run until the reflux ratio becomes so high that product collection is minimal. At this point the

operation is switched to the constant reflux mode and continued until the average composition of the distillate drops to the desired level, when the equipment is shut down. Variations on this approach are often required due to equipment limitations. If the column is to be operated manually, then it might be difficult to maintain constant distillate composition. Also, if the column consists of less than five ideal stages, it is more advantageous to operate at constant reflux.

Prior to the initiation of any operational procedure, it is necessary to elaborate an operation schedule that can be used as a guide throughout the run. Although the procedures discussed here can be implemented for columns with a very low level of automation, they can also be used in application programs that run as a part of an automated control loop. One can use simplified calculation methods (e.g. McCabe–Thiele) or resort to more extensive numerical computations if the effect of some variables such as the hold-up is to be taken into account. Independent of the calculational basis, better predictions of the composition profiles can be obtained if the stage efficiencies or at least the overall efficiency is known. Efficiencies depend on the physical properties of the system, particularly the viscosity and the relative volatility, but also on the geometric characteristics of the equipment. Determination of the overall and stage efficiencies can be easily accomplished by running the column at total reflux. When the column has reached

steady state, the composition profiles within the column must be determined. The overall efficiency is easily calculated by stepping off theoretical stages in the McCabe–Thiele diagram between the equilibrium and the operating line, which at total reflux coincides with $y = x$. The number of theoretical stages is determined when the bottom composition is crossed. The Murphree efficiency for stage n receiving liquid from stage $n - 1$ and vapour from stage $n + 1$ is defined as:

$$\eta_M = \frac{y_n - y_{n-1}}{y_n^{\text{eq}} - y_{n-1}} \quad [38]$$

Eqn [38] is a measure of the degree of separation achieved in the vapour going from stage $n + 1$ to stage n and can be visualized in the McCabe–Thiele diagram as a segment ratio, as shown in **Figure 5**. The maximum degree of separation is represented by the difference in the denominator, where the vapour leaving the stage is in equilibrium with the liquid phase of the same stage.

Determination of the vapour-phase composition is often more difficult than liquid and sample ports are generally only provided for the liquid phase. It is therefore useful to define Murphree efficiency of the liquid compositions as:

$$\eta_M = \frac{x_{n+1} - x_n}{x_{n+1} - x_n^{\text{eq}}} \quad [39]$$

Figure 5 Representation of stage efficiencies.

Once the efficiencies are determined, an operation schedule at constant reflux should be prepared. The operation schedule consists of a family of curves where the reflux ratio is plotted as a function of reboiler composition, holding the distillate composition constant as depicted in Figure 6. The curves can easily be generated in a spreadsheet if the equilibrium curve for the system can be regressed as an analytical form, $x = f(y)$. A distillate composition (x_D) is fixed as the fulcrum, around which all the operating lines pivot, as defined for different reflux ratios (R_D), as shown in Figure 7. Since the number of ideal stages is known, the bottoms composition (x_B) is found for each operating line by stepping off these stages between the equilibrium curve and the operating lines. Once x_B is found for a particular operating line, the reflux ratio is changed, thereby defining another operating line, and the procedure is repeated to find the corresponding x_B . In this way, a set of data points (R_D , x_B) corresponding to a fixed distillate composition x_D is determined. The next set is determined by the same procedure, changing the value of x_D . These plots of R_D versus x_B represent the reflux ratio required to achieve a specified distillate composition at a given composition within the reboiler.

The R_D versus x_B curves can either be used in manual operation or integrated into an automated control strategy, where information about the feed drum composition is used to calculate the new required reflux ratio to keep x_D constant. The choice of x_D will depend on the minimum acceptable purity for the product. Sometimes, even when a higher purity is desired, the operating x_D may be imposed by equipment restrictions. The flow rate range of the pumps, for example, might restrict operation to a certain range of the reflux ratio. In this case, switching to

a lower distillate composition will allow longer runs, thus increasing the total amount of product.

Stopping criteria for an industrial distillation is generally dictated by economics. Operating costs accumulate continuously with time, because of energy and labour costs, as discussed above.

Optimization Techniques

Optimization of batch distillation operations is not addressed with the same frequency as the continuous-case counterpart. The likely reason for the scarcity of publications in this area lies in the transient nature of the problem, which introduces a system of differential equations to describe the dynamics. The optimization problem therefore consists of a target functional (see below) to be minimized and a set of constraints embodied by the differential equations for the time-dependent behaviour of material and energy balances and algebraic equations for phase equilibrium and column hydraulics plus additional constraints such as bounds on certain variables. Optimization problems with nonlinear algebraic model equations and constraints can be solved in a straightforward way by nonlinear programming strategies. On the other hand, unconstrained problems with differential equation models can be handled through the calculus of variations. Models that combine both of these features are currently optimized by imposing some level of approximation to the problem. The problems usually reported in the literature for batch distillation can be classified as:

1. Maximum distillate problem: to maximize the amount of distillate of a specified purity for a specified time.

Figure 6 Operation schedule at constant composition. Reflux schedule (based on 45% η overall). X_B is the reboiler composition, X_d is the distillate composition and R_d is the reflux ratio.

Figure 7 Construction of the operation schedule.

2. Minimum time problem: to minimize the batch time needed to produce a prescribed amount of distillate of a specified purity.
3. Maximum profit problem: to maximize a profit function for a specified purity of distillate.

The maximum profit problem for a column operated at constant distillate composition involves the evaluation of the net profit of the column along its batch run time. The net profit function behaviour has already been discussed. The profit curve displays an extrema and the profit optimization problem therefore seeks the value of the batch run time (a number) that will maximize the net profit function. It is amenable to a simple graphic solution that can be obtained from a spreadsheet as long as a simple zero hold-up model is employed to describe the column operation. On the other hand, the solution of the maximum distillate problem is given by a time-dependent function (the distillate flow rate) that will maximize the cumulative distillate production, a function of the distillate flow rate. This latter function of another function is called a functional.

In this section some of the recently developed techniques to extremize functionals are briefly reviewed. The objective is to offer the reader an introduction to the theme, and provide useful references for further information. The optimization problem belonging to one of the above categories can be posed in terms of an objective function subjected to constraints such as:

$$\text{Min}_{u(t), z(t), p} \Phi = \Psi(z(b), p) + \int_a^b G(z(t), u(t), p) dt \quad [40]$$

subject to:

$$\dot{z}(t) = F(z(t), u(t), p) \quad [41]$$

$$g(u(t), z(t)) \leq 0 \quad [42]$$

$$g_f(z(b)) \leq 0 \quad [43]$$

$$z(a) = z_0 \quad [44]$$

$$z(t)^L \leq z(t) \leq z(t)^U \quad [45]$$

$$u(t)^L \leq u(t) \leq u(t)^U \quad [46]$$

In the above set of equations the integral part of the objective function to be minimized can be viewed as the total amount of distillate, withdrawn as top product, whereas the function $\psi(z(b), p)$ may account for the final hold-up within the equipment, which can be incorporated into the product at the end of a batch run. The vector $z(t)$ represents the state variables of the system, such as composition, internal flow rates and temperatures, and the vector p represents constant parameters. The vector $u(t)$ carries the control profiles, i.e. the variables used to manipulate eqn [40] and achieve the minimization goal. Distillate of a specified purity can be maximized for instance by changing the reflux ratio. The time-dependent reflux ratio would be then the control variable $u(t)$ for such an optimization problem. The constraints represented by eqn [41] embody the material and energy balances, which are written in their transient form for the batch problem. Algebraic constraints included in eqn [42] may represent the equilibrium relations and the summation of the liquid mole fractions. Inequality constraints with lower and upper bounds (eqns [45] and [46]) may represent either purity requirements in the product or physical constraints in the maximum and minimum attainable values of the control variables. Initial and final states of the system are also written as constraints, as represented by eqns [44] and [43] respectively.

The optimal control problem posed above seeks the time-dependent control profile (control function) that minimizes the objective functional (i.e. a function of functions represented by eqn [40]). It can be solved in a variety of ways, depending on how one chooses to handle the differential equation constraints. Methods based on the calculus of variations use Lagrange multipliers and slack variables to restate the constrained problem of eqns [40]–[46] as an unconstrained one. Since the minimum of the constrained problem is equivalent to the minimum of the unconstrained one, the augmented problem is

represented by:

$$\begin{aligned} \text{Min}_{u(t), z(t), p} \Phi^1 = & \psi(z(b), p) + v^T g_f(z(b)) \\ & + \int_a^b [G(z(t), u(t), p) \\ & + \lambda^T(t)(F(z(t), u(t), p) - \dot{z}(t)) \\ & + M^T(t)(g(u(t), z(t)) + s^2)] dt \end{aligned} \quad [47]$$

By analogy to Hamilton's equation of motion, one can define a Hamiltonian as:

$$\begin{aligned} H(z(t), u(t), p) = & G(z(t), u(t), p) + \lambda^T F(z(t), u(t), p) \\ & + M^T(g(u(t), z(t)) + s^2) \end{aligned} \quad [48]$$

And therefore the problem in [47] becomes:

$$\begin{aligned} \text{Min}_{u(t), z(t), p} \Phi^1 = & \psi(z(b), p) + v^T g_f(z(b)) \\ & + \int_a^b [H(z(t), u(t), p) - \lambda(t)\dot{z}(t)] dt \end{aligned} \quad [49]$$

The minimum of the latter is found in the usual way by taking the derivatives of the augmented problem with respect to all the independent variables (z , v , λ , s , u , t). Setting those to zero and taking into account the conditions for a fixed initial condition problem ($dt|_{t_0} = 0$, $dz|_{t_0} = 0$), one obtains the following variational formulation.

State equations

$$\dot{z} = \frac{\partial H}{\partial \lambda} \quad [50]$$

Co-state equations

$$-\dot{\lambda} = \frac{\partial H}{\partial z} \quad [51]$$

Stationary condition

$$\frac{\partial H}{\partial u} = 0 \quad [52]$$

$$\frac{\partial H}{\partial M} = 0 \quad [53]$$

$$\frac{\partial H}{\partial s} = 0 \quad [54]$$

Pontryagin's maximum principle

$$H(x^*, u^*, \lambda^*, t) \leq H(x^*, u^* + \delta u, \lambda^*, t) \quad [55]$$

Boundary condition

$$(\phi_z + \psi_z^T v - \lambda)^T|_b dz(b) + (\phi_t + \psi_t^T v + H)|_b dt(b) = 0 \quad [56]$$

For problems with constraints in the control variables like those given by eqn [46], the stationary condition must be modified to include Pontryagin's maximum principle which establishes that the solution values for the constrained control variables must lie along an optimal path. That is, any variation in the optimal control profile $u^*(t)$ at time t , while keeping the state and co-state variables $z(t)$, $\lambda(t)$ and $M(t)$ at their optimal values, will force an increase in the value of the Hamiltonian. This replaces the unconstrained minimum condition of eqn [52] and is stated mathematically in eqn [55]. Also, the second term of the boundary condition in eqn [56] vanishes for fixed-time problems.

Solution of the optimization problem of eqns [40]–[46] in its variational formulation requires integration of two sets of differential equations given by [50] and [51] to get the state variables z and adjoint variables λ for the ordinary differential equation (ODE). Since these equations are also a function of the control profile $u(t)$, their integration is first performed with guessed values of this vector. Eqns [53] and [54] are used to find the second set of adjoint variables (M) and the slack variables (s^2) associated with the constraint on $g(u(t), z(t))$. Finally, eqn [52] or [55] provides the updated values for $u(t)$, the control profile, whereas the adjoint variables for the boundary conditions are calculated from eqn [56]. The whole procedure involves successive iterations of the control vector and can be computationally intensive, especially for problems with many constraints.

An alternative solution can be formulated to overcome the difficulty posed by the differential constraints. Eqns [40]–[46] are discretized using finite elements. Within each element, function approximation is expressed in terms of orthogonal polynomials and the resulting problem is amenable to a mathematical treatment intended to minimization problems involving only algebraic equations.

Discretization of the optimal control problem leads to the nonlinear problem model given below. This formulation consists of the discretized objective function of the original problem, the continuity equations for state variables and inequality constraints in the

original formulation.

$$\text{Min}_{u_{ij}, z_{ij}, p, \Delta \zeta_i} \Phi = \psi(z_f, p) + \sum_{i=1}^{NE} \sum_{j=1}^K w_{ij} G(z_{ij}, u_{ij}, p, \Delta \zeta_i) \quad [57]$$

subject to:

$$\Delta \zeta_i r_{ij} = \dot{z}_{K+1} \tau_{ij} - \Delta \zeta_i F(z_{ij}, u_{ij}, p) = 0 \quad [58]$$

$$g(u_{ij}, z_{ij}, \Delta \zeta_i) \leq 0 \quad [59]$$

$$g_f(z_f) \leq 0 \quad [60]$$

$$z_{10} - z_0 = 0 \quad [61]$$

$$z_{i0} - z_{K+1}^{i-1}(\zeta_i) = 0 \quad i = 2, \dots, NE \quad [62]$$

$$z_f - z_{K+1}^{NE}(\zeta_{NE+1}) = 0 \quad [63]$$

$$z_{ij}^L \leq z_{ij} \leq z_{ij}^U \quad [64]$$

$$u_{ij}^L \leq u_{ij} \leq u_{ij}^U \quad [65]$$

$$\sum_{i=1}^{NE} \Delta \zeta_i = \zeta_{\text{Total}} \quad [66]$$

Problem discretization introduces the time element lengths ($\Delta \zeta_i$) as additional variables. Thus, variables in [57]–[66] include: $\Delta \zeta_i$, the finite element lengths for $i = 1, \dots, NE$; z_f , the value of the state at the final time; z_{ij} and u_{ij} , the collocation coefficients for the state and control profiles where i refers to the element and j to the collocation point within each element; and p , any additional design parameters (such as boil-up rate and final time). In addition, w_{ij} are quadrature weights from the integral in [40]. Lagrange polynomials are applied for the orthogonal collocation within the finite elements. The order of the collocation method should be equal to the index of the system of the state variable differential constraints and algebraic equations. The index is equal to the number of times the algebraic equations must be derived in order to recover the standard form of a first-order ODE.

The solution of eqns [57]–[66] looks for the values of the coefficients z_{ij} and u_{ij} of the polynomial approximation for the state variables and control profiles respectively. In addition, the discretized problem also includes the length of the discretization interval $\Delta \zeta_i$. The problem variables are partitioned into a set of state variables (z_{ij}) and optimization variables (u_{ij} and $\Delta \zeta_i$), which provides a solution strategy where the state variables are calculated separately using the state equations, whereas the control profile and element lengths are obtained via the solution of a quad-

ratic programming problem as follows (see Logsdon and Biegler, in the Further Reading section):

Equation [58] is solved in each element for the values of z_{ij} in the interior collocation points, starting with the first element, from the initial values of the state variables and guessed element lengths ($\Delta \zeta_i$) and control profiles (u_{ij}). The rightmost (exterior) collocation point for the state and control profiles in eqn [58] is calculated from the values at the interior collocation points by:

$$z_{i,k+1} = \sum_{j=0}^k z_{ij} \phi_j \quad [67]$$

$$u_{i,k+1} = \sum_{j=1}^k z_{ij} \theta_j \quad [68]$$

where ϕ_j and θ_j in the above equation are Legendre's orthogonal polynomials.

Continuity for the state variables is ensured by eqn [62] which establishes the equality between the state variables of the rightmost collocation point of element $i - 1$ and their initial value in element i . The initial value problem presented in eqn [58] is thus integrated element-by-element using a marching technique with collocation within each element.

After a new set of state variables is generated by the technique described above, the control profiles (u_{ij}) and element lengths ($\Delta \zeta_i$) are updated using a successive quadratic programming algorithm that solves the following:

$$\text{Min}_{\Delta \zeta} \nabla \Phi^T \mathbf{Z} \Delta \zeta + \frac{1}{2} \Delta \zeta^T (\mathbf{Z}^T \mathbf{B} \mathbf{Z}) \Delta \zeta \quad [69]$$

subject to:

$$\mathbf{g} + \nabla \mathbf{g}^T \mathbf{Z} \Delta \zeta \leq 0 \quad [70]$$

In the above problem, the variables u and $\Delta \zeta$ were included in the vector $\Delta \zeta$ and the inequality constraint is the same as that of the original problem formulation. ($\mathbf{Z}^T \mathbf{B} \mathbf{Z}$ is the Hessian matrix of the objective function Φ and it is also updated during the quadratic programming step using the BFGS (Broyden–Fletcher–Goldfarb–Shanno) formula). The reduced gradients for the objective and constraint functions appearing in eqns [69] and [70] above are calculated in the iteration t during the integration step according to the formula:

$$\{\mathbf{Z}^T \nabla \Phi\}_j = \frac{\partial z_{t,k+1}}{\partial \zeta_j} \frac{\partial \Phi}{\partial z_t} \quad \{\mathbf{Z}^T \nabla \mathbf{g}_n\}_j = \frac{\partial z_{c,k+1}}{\partial \zeta_j} \frac{\partial \mathbf{g}_n}{\partial z_c} \quad [71]$$

In the equation above, the partial derivatives of the state variables at the rightmost exterior collocation point (z_{k+1}), in relation to the optimized vector ξ , is calculated, via chainruling, by the formula:

$$\frac{\partial z_{i,k+1}}{\partial \xi_j} = \frac{\partial z_{i,k+1}}{\partial z_{i-1,k+1}} \frac{\partial z_{i-1,k+1}}{\partial z_{i-2,k+1}} \dots \frac{\partial z_{i,k+1}}{\partial \xi_j} \quad [72]$$

The new set of control variables and element lengths calculated in the optimization step replaces the old one and the integration step is performed once again. The Kuhn-Tucker conditions, which determine the attainment of constrained minimum, are then checked and the calculations are stopped if these conditions have been reached. Otherwise, the optimization step is performed again and the whole procedure is repeated.

The preceding development typifies the complexity involved in rigorous optimization of batch distillation. The gains of reduced costs or shorter process times that can be achieved by such an optimization would not probably be worth the effort for routine operation. None the less, it is possible to utilize sophisticated laboratory-scale distillation units to test alternative control strategies indicated by computational approaches.

List of Variables

Section 2 – Theory

Variables

b	=	tray hold-up
H	=	molar enthalpy
\bar{D}	=	cumulative distillate production, moles
L	=	liquid molar internal flow rate
\bar{L}	=	cumulative amount of reflux, moles
MW	=	molecular weight
Q	=	heat load
R	=	reflux ratio
S	=	$R/(R + 1)$
T	=	temperature
t	=	time
V	=	vapour molar internal flow rate
v	=	liquid molar volume
Vol	=	volume of the stage
\bar{V}	=	cumulative vapour production, moles
W	=	moles of material left in the still
x	=	liquid molar fraction
y	=	vapour molar fraction

Superscripts

L, V = liquid and vapour phases

Subscripts

i, j	=	tray number, component
i	=	initial
f	=	final
R	=	reboiler
w	=	material in the still
tot	=	total

Section 5 – Optimization Techniques

Variables

a	=	initial condition for the optimization problem
b	=	final condition for the optimization problem
G	=	component of the objective function due to the integral state
H	=	Hamiltonian function
M	=	Lagrange multipliers for the algebraic inequality constraints
p	=	vector of design parameters
t	=	time
s^2	=	vector of slack variables for the inequality constraints
u	=	vector of control variables
z	=	vector of state variables

Superscripts

U, L	=	upper and lower limits of the constrained variables
--------	---	---

Subscripts

z	=	derivative with respect to z
b	=	evaluate at point b

Greek alphabet

$\Delta \xi$	=	vector of time-finite element lengths
θ	=	Lagrange polynomial approximation for the control variables
λ	=	Lagrange multipliers for the differential equality constraints
ν	=	Lagrange multipliers for the inequality constraints at final conditions
ϕ	=	Lagrange polynomial approximation for the state variables
Φ	=	objective function
Ψ	=	term of the objective function evaluated at final conditions

Sublimation

J. D. Green, BP Amoco Chemicals, Hull, UK

This article is reproduced from *Encyclopedia of Analytical Science* Copyright © 1995 Academic Press

Introduction

Sublimation is not a procedure that is generally regarded as an analytical technique. It is a process, however, by which compounds can be purified or mixtures separated and as such can be of value as a single step or as an integral part of a more complex analytical method. It is applicable to a range of solids of inorganic or organic origin in a variety of different matrices and can be particularly useful when heat-labile materials are involved.

As a method of sample purification sublimation has been used to produce high-purity materials as analytical standards. A specific and common example of sublimation used as a means of purification is the removal of water from heat-labile materials in the process known as freeze-drying. The technique is described more fully below.

As a separation technique fractional sublimation has been used either to purify samples for analysis by removing undesirable components of the matrix or to remove the analyte from the matrix for subsequent analysis.

Principles

Sublimation is the direct conversion of a solid to a gas or vapour:

The heat supplied in this endothermic process is termed the heat of sublimation (ΔH_{subl}). The conditions under which sublimation occurs may be predicted for a given substance from its phase diagram, but in practice it is more common to use typical experimental parameters to determine the optimized procedure.

The heat of sublimation is a crucial parameter in deciding upon the applicability of sublimation to a particular substance, or indeed on the possibility of separating two components in a mixture.

An empirical approach to determining the appropriate temperature and pressure for sublimation can be used based upon previously determined data. The temperature (T , °K) and pressure (P) of sublimation can be related by an expression of the form:

$$\log_{10} P \text{ (mmHg)} = A - (B/T)$$

in which the constants A and B for compounds of interest are available from published tables. The

result of the sublimation process can be seen in a freezer where ice sublimates and resolidifies as crystals. Iodine is a common substance that sublimates at room temperature and pressure; the result of this can be observed in a reagent bottle of the element.

The theory and mechanism of sublimation is of less practical importance to analytical procedures than it is in some other specialized areas of chemical science. Knowledge of sublimation characteristics can aid improvements in the stability of materials used at high temperatures or low pressures. For analytical purposes it should be sufficient to recognize that rates of sublimation depend upon the topology of the vaporizing surface (dislocations, atomic steps and ledge concentrations) and upon any atomic rearrangement that occurs during the sublimation process.

Experimentally, to effect sublimation, a number of criteria need to be satisfied. Firstly, the sample in question must be maintained at a temperature that ensures a sufficiently high vapour pressure for sublimation to occur, whilst remaining below that point at which the material either decomposes or melts. Secondly, a secondary surface must be available on which the sublimated vapour can condense or solidify. A number of experimental arrangements have been used that allow these criteria to be established; these are described in a later section of this article. It is also possible to enhance the sublimation process by changing the physical parameters under which the process is carried out:

- The sample may be heated in order to increase its vapour pressure.
- The application of a vacuum to the apparatus encourages vaporization and enhances the sublimation.
- Selectively cooling part of the apparatus increases the efficiency of the condensation process.
- Using an entraining gas can improve the mass transport in the system and thereby increase the overall efficiency of the sublimation process.

Apparatus

The simplest form of sublimation apparatus consists of a beaker or porcelain dish on top of which is placed an upturned watch-glass. The beaker contains the solid to be sublimed and the underside of the watch-glass provides the surface upon which the sublimed components condense (Figure 1). A perforated filter paper is commonly placed between the beaker and the watch-glass to prevent sublimate falling back into the sample.

A variant upon the above system uses an upturned funnel instead of a watch-glass as the condensing

Figure 1 Simple apparatus for demonstrating the principles of sublimation. S, sample; P, sublimate (product); FP, perforated filter paper.

surface and an appropriately placed sealing ring improves the performance (Figure 2). Coils through which coolant is circulated can promote the sublimation process.

An early form of sublimation apparatus of which the above arrangements are derivatives (Figure 3)

Figure 2 Apparatus for simple sublimation at atmospheric pressures. Watch-glass, W, with sample, S, surmounted by filter funnel, FF, with cooling coils, C, glass wool, G, and collected sublimed product, P. A sealing ring, R, is included between the watch-glass and filter funnel.

included a means of cooling the surface on which the sublimate condenses. Cooling can be achieved in a number of ways, for example, using filter papers moistened with cool water, or in the case of the upturned funnel, a suitably shaped coil of circulating coolant liquid can be placed around the surface.

Sublimation under reduced pressure uses a modified form of apparatus in which a sealed enclosure allows a vacuum to be applied. The cooled surface is orientated with respect to the sample so as to maximize the condensation once sublimation has occurred (Figure 4). Reducing the distance that the sublimed substance(s) must travel is beneficial provided the necessary temperature gradient between sample and condensing surface can be maintained. An alternative arrangement for sublimation applications is shown in Figure 5.

Freeze-drying, a special application of the sublimation principle, uses apparatus of a different kind (Figure 6). The sample is dispersed around the walls of a round-bottomed flask whilst it is frozen by immersion in a suitable freezing mixture, for example dry ice-acetone. The flask is then attached to the evacuating system which usually comprises an oil vacuum pump protected from the ice sublimate by a train of condenser traps. Over a period of typically several hours the ice sublimates from the sample and condenses in the traps. Air is then admitted to the apparatus and the dried sample can be removed whilst the sublimed ice is drained off as water through the drain tap. Frequently this system is used to dry heat-sensitive

materials such as enzymes and the process has been termed lyophilization.

Sublimation of metallic elements from rock or ore samples requires high temperatures. The equipment used is based upon silica furnace tubes in order to withstand the necessary conditions. The silica tube is heated in a furnace and the sublimate condenses either on a cool part of the tube or on a cooled surface immediately after leaving the tube.

The conditions of sublimation must be chosen according to the requirements of the application. For simple purification the sample temperature is raised slowly, under reduced pressure if necessary, until sublimate is observed on the condensing surface. These established conditions should then be maintained until no further sublimation appears to be occurring, at which point the sample temperature can be raised again if other components of the sample can be further removed. At any point in this cycle the apparatus can be dismantled and the sublimate removed. This process allows selective separation or fractional sublimation to be carried out.

Applications

Sublimation is applicable to a wide range of organic and inorganic compounds in an equally wide range

Figure 4 Apparatus for sublimation at reduced pressure. Coolant is circulated through the cold finger, CF, whilst a vacuum is applied to the sample chamber.

Figure 5 Improved sublimation apparatus proposed by Eisenbraun *et al.* (1978). Sample, S, sublimates from the lower to the upper chamber where condensation takes place on the cooled surface. A vacuum is applied to the apparatus and cooling coils, C, improve the condensation process. A specially formed spatula, SP, can be used to help remove the sublimate after the upper part of the apparatus is removed.

of different matrices. Sublimable substances include ice, iodine, arsenic(III) oxide, cadmium sulfide, ammonium chloride and a large number of organic compounds. Common matrices from which substances are sublimed include biological fluids, plant materials, carbonaceous materials, samples of crude organic solids and samples of rocks and ores.

Sublimation as a method of applying substances to thin-layer chromatography (TLC) plates involves the sample being sublimed and the vapour produced being directed by means of a drawn capillary onto the surface of a TLC plate which is slowly moved in one dimension. This results in the sublimed materials being deposited upon the TLC plate in a differential

mode – the most easily sublimed compounds are deposited first whilst those requiring a higher temperature are deposited later. The TLC plate is then developed in the normal way to give what has been termed a ‘thermofractogram’ in which the substances are separated as a function of their heats of sublimation along one axis and as a function of their chromatographic characteristics along the other axis. This approach has been applied to a wide range of substances including pharmaceutical preparations, plant components and foodstuffs.

Only a very limited number of standard methods have been reported in which sublimation is an important aspect. These comprise an ASTM standard for measurement of sublimation from thermionic emitters, and two standards from Germany and Japan testing the stability of dyes and printing inks to sublimation. The first covers the determination of the quantity, rate, and identity of sublimed, evaporated, or sputtered materials, whilst the latter two are concerned with textile materials and semi-manufactured products.

Sublimation is often the mechanism by which pre-concentration of an analyte is effected, although this fact is frequently not appreciated. Dynamic headspace concentration from solid samples such as plant materials, foodstuffs or polymeric materials occurs by sublimation of the volatile components. Indeed, given appropriate apparatus that can be operated at different temperatures for dynamic

Figure 6 Typical freeze-drying apparatus. The frozen sample, S, is attached to the condenser assembly and a vacuum is applied. A cold trap, CT, protects the pump as ice sublimates from the sample and subsequently condenses in the refrigerant condensers, RC. On completion of the drying the sample is removed and the collected ice melts and drains from the system through the stopcock, SC.

headspace concentration, the heat of sublimation can be determined for various compounds.

Derivatization procedures carried out on crude samples can produce materials with improved sublimation characteristics. This technique has been used to produce volatile compounds of lanthanides and actinides which have then been sublimed prior to analytical determinations. Derivatives have been made using β -diketones (hexafluoroacetylacetone or acetylacetone), benzoyltrifluoroacetone and thenoyltrifluoroacetones.

Low-temperature sublimation, which in some circumstances is termed freeze-drying, has been used to separate water, as ice, from biological fluids such as serum, urine or saliva. The technique has been particularly useful in paediatric cases where sample volumes are extremely low. Determinations have then been accomplished using IR spectroscopy or mass spectrometry. Preparation of physiological samples for determination of deuterium oxide has included sublimation techniques prior to spectrophotometric determinations.

Low-temperature sublimation has been used to prepare samples for cryo-scanning electron microscopy (SEM) analysis in order to examine herbicide particles in a water suspension. The sublimation of herbicide-containing frozen water droplets provides a suitable etching of the surface for the SEM technique.

High-temperature sublimations are often the methods of choice in sample preparations from mineral ores, particularly in the case of trace enrichment of noble metals and the actinides and lanthanides prior to activation methods. Temperatures of 800–1200°C are typical. The procedure is carried out in silica tubes with entrainment gases, for example air or argon, being used to increase the sublimation process.

Polycyclic aromatic compounds have been separated using sublimation techniques from a variety of samples including coal, solids derived from oil, coal and petroleum processing, and residues (soots) resulting from the use of such fossil fuels.

A variety of miscellaneous applications have been developed for separation from difficult matrices and purification of specific materials. These include:

- Mercury separated from impurities by conversion to its iodide followed by sublimation.
- Isolation of proazulene and chamomile from the flower heads of plants.
- Isolation of aroma compounds from wheat and rye samples prior to determination using isotope dilution methods.
- Determination of tin in cassiterite.
- Selective sublimation of molybdenum and tungsten.

Sublimation is used in some procedures for the preparation of samples for SEM in which gold is sublimed in vacuum from a heated tungsten filament to the sample being examined.

Theory of Distillation

Introduction

Distillation is a very old separation technology for separating liquid mixtures that can be traced back to

the chemists in Alexandria in the first century AD. Today distillation is the most important industrial separation technology. It is particularly well suited for high purity separations since any degree of separation can be obtained with a fixed energy consumption by increasing the number of equilibrium stages.

To describe the degree of separation between two components in a column or in a column section, we

introduce the separation factor:

$$S = \frac{(x_L/x_H)_T}{(x_L/x_H)_B} \quad [1]$$

where x denotes mole fraction of a component, subscript L denotes light component, H heavy component, T denotes the top of the section, and B the bottom.

It is relatively straightforward to derive models of distillation columns based on almost any degree of detail, and also to use such models to simulate the behaviour on a computer. However, such simulations may be time-consuming and often provide limited insight. The objective of this article is to provide analytical expressions that are useful for understanding the fundamentals of distillation and which may be used to guide and check more detailed simulations:

1. minimum energy requirement and corresponding internal flow requirements
2. minimum number of stages
3. simple expressions for the separation factor

The derivation of analytical expressions requires the assumptions of:

1. equilibrium stages
2. constant relative volatility
3. constant molar flows

These assumptions may seem restrictive, but they are actually satisfied for many real systems, and in any case the resulting expressions yield invaluable insights, also for systems where the approximations do not hold.

Fundamentals

The Equilibrium-Stage Concept

The equilibrium (theoretical)-stage concept (Figure 1) is central in distillation. Here we assume vapour-liquid equilibrium (VLE) on each stage and that the liquid is sent to the stage below and the vapour to the stage above. For some trayed columns this may be a reasonable description of the actual physics, but it is certainly not for a packed column. Nevertheless, it is established that calculations based on the equilibrium-stage concept (with the number of stages adjusted appropriately) fits data from most real columns very well, even packed columns.

One may refine the equilibrium stage concept, e.g. by introducing back-mixing or a Murphree efficiency factor for the equilibrium, but these 'fixes' often have relatively little theoretical justification, and are not used in this article.

For practical calculations, the critical step is usually not the modelling of the stages, but to obtain a good description of the VLE. In this area there has been significant advances in the last 25 years, especially after the introduction of equations of state for VLE prediction. However, here we will use simpler VLE models (constant relative volatility) which apply to relatively ideal mixtures.

Vapour-Liquid Equilibrium

In a two-phase system ($PH = 2$) with N_c nonreacting components, the state is completely determined by N_c degrees of freedom (f), according to Gibb's phase rule:

$$f = N_c + 2 - PH \quad [2]$$

Figure 1 Equilibrium-stage concept.

If the pressure (P) and $N_c - 1$ liquid compositions or mole fractions (x) are used as degree of freedom, then the mole fractions (y) in the vapour phase and the temperature (T) are determined, provided that two phases are present. The general VLE relation can then be written:

$$\begin{aligned} [y_1, y_2 \dots y_{N_c-1}, T] &= f(P, x_1, x_2 \dots x_{N_c-1}) \\ [y, T] &= f(P, x) \end{aligned} \quad [3]$$

Here we have introduced the mole fractions x and y in the liquid and vapour phases respectively, and we trivially have $\sum_{i=1}^n x_i = 1$ and $\sum_{i=1}^n y_i = 1$.

In ideal mixtures, the VLE can be derived from Raoult's law which states that the partial pressure p_i of a component (i) in the vapour phase is proportional to the vapour pressure (p_i^o) of the pure component (which is a function of temperature only: $p_i^o = p_i^o(T)$) and the liquid mole fraction (x_i):

$$p_i = x_i p_i^o(T) \quad [4]$$

For an ideal gas, according to Dalton's law, the partial pressure of a component is proportional to the mole fraction $p_i = y_i P$ and since the total pressure $P = p_1 + p_2 + \dots + p_{N_c} = \sum_i p_i = \sum_i x_i p_i^o(T)$ we derive:

$$y_i = x_i \frac{p_i^o}{P} = \frac{x_i p_i^o(T)}{\sum_i x_i p_i^o(T)} \quad [5]$$

The following empirical formula is frequently used to compute the pure component vapour pressure:

$$\ln p^o(T) \approx a + \frac{b}{c + T} + d \ln(T) + eT^f \quad [6]$$

The coefficients are listed in component property databases. The case with $d = e = 0$ is called the Antoine equation.

K-values and Relative Volatility

The K -value for a component i is defined as: $K_i = y_i/x_i$. The K -value is sometimes called the equilibrium constant, but this is misleading as it depends strongly on temperature and pressure (or composition).

The relative volatility between components i and j is defined as:

$$\alpha_{ij} = \frac{(y_i/x_i)}{(y_j/x_j)} = \frac{K_i}{K_j} \quad [7]$$

For ideal mixtures that satisfy Raoult's law we have:

$$\alpha_{ij} = \frac{(y_i/x_i)}{(y_j/x_j)} = \frac{K_i}{K_j} = \frac{p_i^o(T)}{p_j^o(T)} \quad [8]$$

Here $p_i^o(T)$ depends on temperature so the K -values will actually be constant only close to the column ends where the temperature is relatively constant. On the other hand, the ratio $p_i^o(T)/p_j^o(T)$ is much less dependent on temperature, which makes the relative volatility very attractive for computations. For ideal mixtures, a geometric average of the relative volatilities for the highest and lowest temperature in the column usually gives sufficient accuracy in the computations: $\alpha_{ij} = \sqrt{\alpha_{ij, \text{top}} \cdot \alpha_{ij, \text{bottom}}}$.

We usually select a common reference component r (usually the least volatile or heavy component), and define:

$$\alpha_i = \alpha_{ir} = p_i^o(T)/p_r^o(T) \quad [9]$$

The VLE relationship (eqn [5]) then becomes:

$$y_i = \frac{\alpha_i x_i}{\sum_i \alpha_i x_i} \quad [10]$$

For a binary mixture we usually omit the component index for the light component, i.e. we write $x = x_1$ (light component) and $x_2 = 1 - x$ (heavy component). Then the VLE relationship becomes:

$$y = \frac{\alpha x}{1 + (\alpha - 1)x} \quad [11]$$

This equilibrium curve is illustrated in Figure 2.

The difference $y - x$ determines the amount of separation that can be achieved on a stage. Large relative volatilities imply large differences in boiling points and easy separation. Close boiling points imply relative volatility closer to unity, as shown below quantitatively.

Estimating the Relative Volatility from Boiling Point Data

The Clapeyron equation relates the vapour pressure temperature dependency to the specific heat of vaporization (ΔH^{vap}) and volume change between liquid and vapour phase (ΔV^{vap}):

$$\frac{dp^o(T)}{dT} = \frac{\Delta H^{\text{vap}}(T)}{T \Delta V^{\text{vap}}(T)} \quad [12]$$

Figure 2 VLE for ideal binary mixture: $y = \alpha x/1 + (\alpha - 1)x$.

If we assume an ideal gas phase, and that the gas volume is much larger than the liquid volume, then $\Delta V^{\text{vap}} \approx RT/P$, and integration of Clapeyron's equation from temperature T_{bi} (boiling point at pressure P_{ref}) to temperature T (at pressure p_i°) gives, when ΔH_i^{vap} is assumed constant:

$$\ln p_i^{\circ} \approx \left(\frac{\Delta H_i^{\text{vap}}}{R} \left(\frac{1}{T_{\text{bi}}} \right) + \ln P_{\text{ref}} \right) + \frac{\left(-\frac{\Delta H_i^{\text{vap}}}{R} \right)}{T} \quad [13]$$

This gives us the Antoine coefficients: $a_i = (\Delta H_i^{\text{vap}}/R) (1/T_{\text{bi}}) + \ln P_{\text{ref}}$, $b_i = -\Delta H_i^{\text{vap}}/R$, $c_i = 0$. In most cases $P_{\text{ref}} = 1$ atm. For an ideal mixture that satisfies Raoult's law we have $\alpha_{ij} = p_i^{\circ}(T)/p_j^{\circ}(T)$ and we derive:

$$\ln \alpha_{ij} = \frac{\Delta H_i^{\text{vap}}}{R} \frac{1}{T_{\text{bi}}} - \frac{\Delta H_j^{\text{vap}}}{R} \frac{1}{T_{\text{bj}}} + \frac{\Delta H_j^{\text{vap}} - \Delta H_i^{\text{vap}}}{RT} \quad [14]$$

We see that the temperature dependency of the relative volatility arises from different specific heats of vaporization. For similar values ($\Delta H_i^{\text{vap}} \approx \Delta H_j^{\text{vap}}$), the expression simplifies to:

$$\ln \alpha_{ij} \approx \underbrace{\frac{\Delta \bar{H}^{\text{vap}}}{R \bar{T}_b}}_{\beta} \frac{T_{\text{bj}} - T_{\text{bi}}}{\bar{T}_b} \quad \text{where } \bar{T}_b = \sqrt{T_{\text{bi}} T_{\text{bj}}} \quad [15]$$

Here we may use the geometric average also for the heat of vaporization:

$$\Delta \bar{H}^{\text{vap}} = \sqrt{\Delta H_i^{\text{vap}}(T_{\text{bi}}) \cdot \Delta H_j^{\text{vap}}(T_{\text{bj}})}$$

This results in a rough estimate of the relative volatility α_{ij} , based on the boiling points only:

$$\alpha_{ij} \approx e^{\beta(T_{\text{bj}} - T_{\text{bi}})/\bar{T}_b} \quad \text{where } \beta = \frac{\Delta \bar{H}^{\text{vap}}}{R \bar{T}_b} \quad [16]$$

If we do not know $\Delta \bar{H}^{\text{vap}}$, a typical value $\beta \approx 13$ can be used for many cases.

Example For methanol (*L*) and *n*-propanol (*H*), we have $T_{\text{BL}} = 337.8$ K and $T_{\text{BH}} = 370.4$ K and the heats of vaporization at their boiling points are 35.3 and 41.8 kJ mol⁻¹ respectively. Thus $\bar{T}_b = \sqrt{337.8 \cdot 370.4} = 354$ K and $\Delta \bar{H}^{\text{vap}} = \sqrt{35.3 \cdot 41.8} = 38.4$. This gives $\beta = \Delta \bar{H}^{\text{vap}}/R \bar{T}_b = 38.4/(8.83 \cdot 354) = 13.1$ and $\alpha \approx e^{13.1 \cdot 32.6/354} \approx 3.34$ which is a bit lower than the experimental value.

Material Balance on a Distillation Stage

Based on the equilibrium-stage concept, a distillation column section is modelled as shown in Figure 3.

Figure 3 Distillation column section modelled as a set of connected equilibrium stages.

Note that we choose to number the stages starting from the bottom of the column. We denote L_n and V_n as the total liquid and vapour molar flow rates leaving stage n (and entering stages $n-1$ and $n+1$, respectively). We assume perfect mixing in both phases inside a stage. The mole fraction of species i in the vapour leaving the stage with V_n is $y_{i,n}$, and the mole fraction in L_n is $x_{i,n}$.

The material balance for component i at stage n then becomes (in mol s^{-1}):

$$\frac{dN_{i,n}}{dt} = (L_{n+1}x_{i,n+1} - V_n y_{i,n}) - (L_n x_{i,n} - V_{n-1} y_{i,n-1}) \quad [17]$$

where $N_{i,n}$ is the number of moles of component i on stage n . In the following we will consider steady-state operation, i.e.: $dN_{i,n}/dt = 0$.

It is convenient to define the net material flow (w_i) of component i upwards from stage n to $n+1$ (mol s^{-1}):

$$w_{i,n} = V_n y_{i,n} - L_{n+1} x_{i,n+1} \quad [18]$$

At steady state, this net flow has to be the same through all stages in a column section, i.e. $w_{i,n} = w_{i,n+1} = w_i$.

The material flow equation is usually rewritten to relate the vapour composition (y_n) on one stage to the

liquid composition on the stage above (x_{n+1}):

$$y_{i,n} = \frac{L_{n+1}}{V_n} x_{i,n+1} + \frac{1}{V_n} w_i \quad [19]$$

The resulting curve is known as the operating line. Combined with the VLE relationship (equilibrium line), this enables us to compute all the stage compositions when we know the flows in the system. This is illustrated in **Figure 4**, and forms the basis of McCabe–Thiele approach.

Assumption about Constant Molar Flows

In a column section, we may very often use the assumption about constant molar flows. That is, we assume $L_n = L_{n+1} = L$ (mol s^{-1}) and $V_{n-1} = V_n = V$ (mol s^{-1}). This assumption is reasonable for ideal mixtures when the components have similar molar heats of vaporization. An important implication is that the operating line is then a straight line for a given section, i.e. $y_{i,n} = (L/V)x_{i,n+1} + w_i/V$. This makes computations much simpler since the internal flows (L and V) do not depend on compositions.

The Continuous Distillation Column

We study here the simple two-product continuous distillation column in **Figure 5**. We will first limit ourselves to a binary feed mixture, and the component index is omitted, so the mole fractions (x, y, z) refer to the light component. The column has N equilibrium stages, with the reboiler as stage number 1. The feed with total molar flow rate F (mol s^{-1}) and mole fraction z enters at stage N_F .

The section above the feed stage is denoted the rectifying section, or just the top section, and the most volatile component is enriched upwards towards the distillate product outlet (D). The stripping section, or the bottom section, is below the feed, in which the least volatile component is enriched towards the bottoms product outlet (B). (The least volatile component is stripped out.) Heat is supplied in the reboiler and removed in the condenser, and we do not consider any heat loss along the column.

The feed liquid fraction q describes the changes in liquid and vapour flow rates at the feed stage:

$$\Delta L_F = qF \quad [20]$$

$$\Delta V_F = (1 - q) F$$

Figure 4 Combining the VLE and the operating line to compute mole fractions in a section of equilibrium stages.

The liquid fraction is related to the feed enthalpy (h_F) as follows:

$$q = \frac{h_{V,\text{sat}} - h_F}{\Delta H^{\text{vap}}} = \begin{cases} > 1 & \text{Subcooled liquid} \\ = 1 & \text{Saturated liquid} \\ 0 < q < 1 & \text{Liquid and vapour} \\ = 0 & \text{Saturated vapour} \\ < 0 & \text{Superheated vapour} \end{cases} \quad [21]$$

When we assume constant molar flows in each section, we get the following relationships for the flows:

$$\begin{aligned} V_T &= V_B + (1 - q)F \\ L_B &= L_T + qF \\ D &= V_T - L_T \\ B &= L_B - V_B \end{aligned} \quad [22]$$

Degrees of Freedom in Operation of a Distillation Column

With a given feed (F , z and q), and column pressure (P), we have only 2 degrees of freedom in operation of the two-product column in Figure 5, independent of the number of components in the feed. This may be a bit confusing if we think about degrees of freedom as in Gibb's phase rule, but in this context Gibb's rule

does not apply since it relates the thermodynamic degree of freedom inside a single equilibrium stage.

This implies that if we know, for example, the reflux (L_T) and vapour (V_B) flow rate into the column, all states on all stages and in both products are completely determined.

External and Internal Flows

The overall mass balance and component mass balance is given by:

$$F = D + B \quad [23]$$

$$Fz = Dx_D + Bx_B$$

Here z is the mole fraction of light component in the feed, and x_D and x_B are the product compositions. For sharp splits with $x_D \approx 1$ and $x_B \approx 0$ we then have that $D = zF$. In words, we must adjust the product split D/F such that the distillate flow equals the amount of light component in the feed. Any deviation from this value will result in large changes in product composition. This is a very important insight for practical operation.

Example Consider a column with $z = 0.5$, $x_D = 0.99$, $x_B = 0.01$ (all these refer to the mole fraction of light component) and $D/F = B/F = 0.5$. To simplify the discussion set $F = 1$ (mol s⁻¹). Now consider a 20% increase in the distillate D from 0.51 to

Figure 5 An ordinary continuous two-product distillation column.

$0.6 \text{ (mol s}^{-1}\text{)}$. This will have a drastic effect on composition. Since the total amount of light component available in the feed is $z = 0.5 \text{ (mol s}^{-1}\text{)}$, at least $0.1 \text{ (mol s}^{-1}\text{)}$ of the distillate must now be heavy component, so the amount mole fraction of light component is now at its best $0.5/0.6 = 0.833$. In other words, the amount of heavy component in the distillate will increase at least by a factor of 16.7 (from 1% to 16.7%).

Thus, we generally have that a change in external flows (D/F and B/F) has a large effect on composition, at least for sharp splits, because any significant deviation in D/F from z implies large changes in composition. On the other hand, the effects of changes in the internal flows (L and V) are much smaller.

McCabe–Thiele Diagram (Constant Molar Flows, but any VLE)

The McCabe–Thiele diagram where y is plotted as a function x along the column provides an insightful graphical solution to the combined mass balance (operation line) and VLE (equilibrium line) equations. It is mainly used for binary mixtures. It is often used to

find the number of theoretical stages for mixtures with constant molar flows. The equilibrium relationship $y_n = f(x_n)$ (y as a function of x at the stages) may be nonideal. With constant molar flow, L and V are constant within each section and the operating lines (y as a function of x between the stages) are straight. In the top section the net transport of light component $w = x_D D$. Inserted into the material balance eqn [19] we obtain the operating line for the top section, and we have a similar expression for the bottom section:

$$\text{Top: } y_n = \left(\frac{L}{V}\right)_T (x_{n+1} - x_D) + x_D \quad [24]$$

$$\text{Bottom: } y_n = \left(\frac{L}{V}\right)_B (x_{n+1} - x_B) + x_B$$

A typical McCabe–Thiele diagram is shown in Figure 6.

The optimal feed stage is at the intersection of the two operating lines and the feed-stage composition (x_F, y_F) is then equal to the composition of the flashed feed mixture. We have that $z = qx_F + (1 - q)y_F$. For $q = 1$ (liquid feed) we find $x_F = z$ and for $q = 0$ (vapour feed) we find $y_F = z$ (in the other cases we must solve the equation together with the VLE). The pinch, which occurs at one side of the feed stage if the feed is not optimally located, is easily understood from the McCabe–Thiele diagram, as shown in Figure 8 (see below).

Typical Column Profiles – Pinch

An example of a column composition profile is shown in Figure 7 for a column with $z = 0.5$, $\alpha = 1.5$, $N = 40$, $N_F = 21$ (counted from the bottom, including the reboiler), $y_D = 0.90$, $x_B = 0.002$. This is a case where the feed stage is not optimally located, as seen from the presence of a pinch zone (a zone of constant composition) above the stage. The corresponding McCabe–Thiele diagram is shown in Figure 8. We see that the feed stage is not located at the intersection of the two operating lines, and that there is a pinch zone above the feed, but not below.

Simple Design Equations

Minimum Number of Stages – Infinite Energy

The minimum number of stages for a given separation (or equivalently, the maximum separation for a given number of stages) is obtained with infinite internal flows (infinite energy) per unit feed. (This always holds for single-feed columns and ideal

Figure 6 McCabe–Thiele diagram with an optimally located feed.

mixtures, but may not hold, for example, for extractive distillation with two feed streams.)

With infinite internal flows (total reflux) $L_n/F = \infty$ and $V_n/F = \infty$, a material balance across any part of the column gives $V_n = L_{n+1}$, and similarly a material balance for any component gives $V_n y_n = L_{n+1} x_{n+1}$. Thus, $y_n = x_{n+1}$, and with constant relative volatility

we have:

$$\alpha = \frac{y_{L,n}/x_{L,n}}{y_{H,n}/x_{H,n}} = \frac{x_{L,n+1}/x_{L,n}}{x_{H,n+1}/x_{H,n}} \quad [25]$$

For a column or column section with N stages, repeated use of this relation gives directly Fenske's

Figure 7 Composition profile (x_L , x_H) for case with nonoptimal feed location. Continuous line, light key; dashed line, heavy key.

Figure 8 McCabe-Thiele diagram for the same example as shown in Figure 7. Observe that the feed stage location is not optimal.

formula for the overall separation factor:

$$S = \left(\frac{x_L}{x_H} \right)_T / \left(\frac{x_L}{x_H} \right)_B = \alpha^N \quad [26]$$

For a column with a given separation, this yields Fenske's formula for the minimum number of stages:

$$N_{\min} = \frac{\ln S}{\ln \alpha} \quad [27]$$

These Fenske expressions do not assume constant molar flows and apply to the separation between any two components with constant relative volatility. Note that although a high purity separation (large S) requires a larger number of stages, the increase is only proportional to the logarithm of the separation factor. For example, increasing the purity level in a product by a factor of 10 (e.g. by reducing $x_{H,D}$ from 0.01 to 0.001) increases N_{\min} by about a factor of $\ln 10 = 2.3$.

A common rule of thumb is to select the actual number of stages $N = 2N_{\min}$ (or even larger).

Minimum Energy Usage – Infinite Number of Stages

For a given separation, an increase in the number of stages will yield a reduction in the reflux (or equiva-

lently in the boil-up). However, as the number of stages approaches infinity, a pinch zone develops somewhere in the column, and the reflux cannot be reduced further. For a binary separation the pinch usually occurs at the feed stage (where the material balance line and the equilibrium line will meet), and we can easily derive an expression for the minimum reflux with $N = \infty$. For a saturated liquid feed ($q = 1$) (King's formula):

$$L_{T\min} = \frac{r_{L,D} - \alpha r_{H,D}}{\alpha - 1} F \quad [28]$$

where $r_{L,D} = x_{L,D}/zF$ is the recovery fraction of light component, and $r_{H,D}$ of heavy component, both in the distillate. The value depends relatively weakly on the product purity, and for sharp separations (where $r_{L,D} = 1$ and $r_{H,D} = 0$), we have $L_{T\min} = F/(\alpha - 1)$. Actually, eqn [28] applies without stipulating constant molar flows or constant α , but then $L_{T\min}$ is the liquid flow entering the feed stage from above, and α is the relative volatility at feed conditions. A similar expression, but in terms of $V_{B\min}$ entering the feed stage from below, applies for a saturated vapour feed ($q = 0$) (King's formula):

$$V_{B\min} = \frac{r_{H,B} - \alpha r_{L,B}}{\alpha - 1} F \quad [29]$$

For sharp separations we get $V_{Bmin} = F/(\alpha - 1)$. In summary, for a binary mixture with constant molar flows and constant relative volatility, the minimum boil-up for sharp separations is:

$$\begin{aligned} \text{Feed liquid, } q = 1: \quad V_{Bmin} &= \frac{1}{\alpha - 1}F + D \\ \text{Feed vapour, } q = 0: \quad V_{Bmin} &= \frac{1}{\alpha - 1}F \end{aligned} \quad [30]$$

Note that minimum boil-up is independent of the product purity for sharp separations. From this we establish one of the key properties of distillation: we can achieve any product purity (even infinite separation factor) with a constant finite energy (as long as it is higher than the minimum) by increasing the number of stages.

Obviously, this statement does not apply to azeotropic mixtures, for which $\alpha = 1$ for some compositions but we can get arbitrarily close to the azeotropic composition, and useful results may be obtained in some cases by treating the azeotrope as a pseudo-component and using α for this pseudo-separation.

Finite Number of Stages and Finite Reflux

Fenske's formula $S = \alpha^N$ applies to infinite reflux (infinite energy). To extend this expression to real columns with finite reflux we will assume constant molar flows and consider three approaches:

1. Assume constant K -values and derive the Kremser formulas (exact close to the column end for a high purity separation.)
2. Assume constant relative volatility and derive the following extended Fenske formula (approximate formula for case with optimal feed-stage location):

$$S \approx \alpha^N \frac{(L_T/V_T)^{N_T}}{(L_B/V_B)^{N_B}}$$

Here N_T is the number of stages in the top section and N_B in the bottom section.

3. Assume constant relative volatility and derive exact expressions. The most used are the Underwood formulas which are particularly useful for computing the minimum reflux (with infinite stages).

Constant K -Values – Kremser Formulas

For high purity separations most of the stages are located in the corner parts of the McCabe–Thiele diagram where, according to Henry's law, we may approximate the VLE relationship, even for nonideal mixtures, by straight lines:

Bottom of column:

$$y_L = H_L x_L \text{ light component; } x_L \rightarrow 0$$

Top of column:

$$y_H = H_H x_H \text{ heavy component; } x_H \rightarrow 0$$

where H is Henry's constant. (For the case of constant relative volatility, Henry's constant in the bottom is $H_L = \alpha$ and in the top is $H_H = 1/\alpha$.) Thus, with constant molar flows, both the equilibrium and mass-balance relationships are linear, and the resulting difference equations are easily solved analytically. For example, at the bottom of the column we derive for the light component:

$$\begin{aligned} x_{L,n+1} &= (V_B/L_B)H_L x_{L,n} + (B/L_B)x_{L,B} \\ &= s x_{L,n} + (1 - V_B/L_B)x_{L,B} \end{aligned} \quad [31]$$

where $s = (V_B/L_B)H_L > 1$ is the stripping factor. Repeated use of this equation gives the Kremser formula for stage N_B from the bottom (the reboiler would here be stage zero):

$$x_{L,N_B} = s^{N_B} x_{L,B} [1 + (1 - V_B/L_B)(1 - s^{-N_B})/(s - 1)] \quad [32]$$

(assuming we are in the region where s is constant, i.e. $x_L \approx 0$). At the top of the column we have for the heavy component:

$$\begin{aligned} y_{H,n-1} &= (L_T/V_T)(1/H_H)y_{H,n} + (D/V_T)x_{H,D} \\ &= a y_{H,n} + (1 - L_T/V_T)x_{H,D} \end{aligned} \quad [33]$$

where $a = (L_T/V_T)/H_H > 1$ is the absorption factor. The corresponding Kremser formula for the heavy component in the vapour phase at stage N_T counted from the top of the column (the accumulator in stage zero) is then:

$$y_{H,N_T} = a^{N_T} x_{H,D} [1 + (1 - L_T/V_T)(1 - a^{-N_T})/(a - 1)] \quad [34]$$

(assuming we are in the region where a is constant, i.e. $x_H \approx 0$).

For hand calculations one may use the McCabe–Thiele diagram for the intermediate composition region, and the Kremser formulas at the column ends where the use of the McCabe–Thiele diagram is inaccurate.

Example We consider a column with $N = 40$, $N_F = 21$, $\alpha = 1.5$, $z_L = 0.5$, $F = 1$, $D = 0.5$, $V_B = 3.206$. The feed is saturated liquid and exact

calculations give the product compositions $x_{H,D} = x_{L,B} = 0.01$. We now want to have a bottom product with only 1 p.p.m. heavy product, i.e. $x_{L,B} = 1.e - 6$. We can use the Kremser formulas to estimate easily the additional stages needed when we have the same energy usage, $V_B = 3.206$. (Note that with the increased purity in the bottom we actually get $D = 0.505$.) At the bottom of the column $H_L = \alpha = 1.5$ and the stripping factor is $s = (V_B/L_B)H_L = (3.206/3.711)1.5 = 1.296$.

With $x_{L,B} = 1.e - 6$ (new purity) and $x_{L,N_B} = 0.01$ (old purity) we find by solving the Kremser equation [31] for the top with respect to N_B that $N_B = 34.1$, and we conclude that we need about 34 additional stages in the bottom (this is not quite enough since the operating line is slightly moved and thus affects the rest of the column; using 36 rather than 34 additional stages compensates for this).

The above Kremser formulas are valid at the column ends, but the linear approximation resulting from the Henry's law approximation lies above the real VLE curve (it is optimistic), and thus gives too few stages in the middle of the column. However, if there is no pinch at the feed stage (i.e. the feed is optimally located), then most of the states in the column will be located at the column ends where the above Kremser formulas apply.

Approximate Formula with Constant Relative Volatility

We will now use the Kremser formulas to derive an approximation for the separation factor S . First note that for cases with high purity products we have $S \approx 1/(x_{L,B}x_{H,D})$. That is, the separation factor is the inverse of the product of the key component product impurities.

We now assume that the feed stage is optimally located such that the composition at the feed stage is the same as that in the feed, i.e. $y_{H,N_T} = y_{H,F}$ and $x_{L,N_B} = x_{L,F}$. Assuming constant relative volatility and using $H_L = \alpha$, $H_B = 1/\alpha$, $\alpha = (y_{L,F}/x_{L,F})/(y_{H,F}/x_{H,F})$ and $N = N_T + N_B + 1$ (including total reboiler) then gives:

$$S \approx \alpha^N \frac{(L_T/V_T)^{N_T}}{(L_B/V_B)^{N_B}} \frac{c}{(x_{H,F}y_{L,F})}$$

where:

$$c = \left[1 + \left(1 - \frac{V_B}{L_B} \right) \frac{(1 - s^{-N_B})}{(s - 1)} \right] \times \left[1 + \left(1 - \frac{L_T}{V_T} \right) \frac{(1 - a^{-N_T})}{(a - 1)} \right]$$

We know that S predicted by this expression is somewhat too large because of the linearized VLE. However, we may correct it such that it satisfies the exact relationship $S = \alpha^N$ at infinite reflux (where $L_B/V_B = V_T/L_T = 1$ and $c = 1$) by dropping the factor $1/(x_{H,F}y_{L,F})$ (which as expected is always larger than 1). At finite reflux, there are even more stages in the feed region and the formula will further overestimate the value of S . However, since $c > 1$ at finite reflux, we may partly counteract this by setting $c = 1$. Thus, we delete the term c and arrive at the final extended Fenske formula, where the main assumptions are that we have constant relative volatility, constant molar flows and that there is no pinch zone around the feed (i.e. the feed is optimally located):

$$S \approx \alpha^N \frac{(L_T/V_T)^{N_T}}{(L_B/V_B)^{N_B}} \quad [35]$$

where $N = N_T + N_B + 1$. Together with the material balance, $Fz_F = Dx_D + Bx_B$, this approximate formula can be used to estimate the number of stages for column design (instead of e.g. the Gilliland plots), and also to estimate the effect of changes of internal flows during column operation. However, its main value is the insight it provides:

1. We see that the best way to increase the separation S is to increase the number of stages.
2. During operation where N is fixed, the formula provides us with the important insight that the separation factor S is increased by increasing the internal flows L and V , thereby making L/V closer to 1. However, the effect of increasing the internal flows (energy) is limited since the maximum separation with infinite flows is $S = \alpha^N$.
3. We see that the separation factor S depends mainly on the internal flows (energy usage) and only weakly on the split D/F . This means that if we change D/F then S will remain approximately constant (Shinskey's rule), that is, we will get a shift in impurity from one product to the other such that the product of the impurities remains constant. This insight is very useful.

Example Consider a column with $x_{D,H} = 0.01$ (1% heavy in top) and $x_{B,L} = 0.01$ (1% light in bottom). The separation factor is then approximately $S = 0.99 \times 0.99 / (0.01 \times 0.01) = 9801$. Assume we slightly increase D from 0.50 to 0.51. If we assume constant separation factor (Shinskey's rule), then we find that $x_{D,H}$ changes from 0.01 to 0.0236 (heavy impurity in the top product increases by a factor 2.4), whereas $x_{B,L}$ changes from 0.01 to 0.0042 (light

impurity in the bottom product decreases by a factor 2.4). Exact calculations with column data: $N = 40$, $N_F = 21$, $\alpha = 1.5$, $z_L = 0.5$, $F = 1$, $D = 0.5$, $L_T/F = 3.206$, given that $x_{D,H}$ changes from 0.01 to 0.0241 and $x_{B,L}$ changes from 0.01 to 0.0046 (separation factor changes from $S = 9801$ to 8706). Thus, Shinsky's rule gives very accurate predictions.

However, the simple extended Fenske formula also has shortcomings. First, it is somewhat misleading since it suggests that the separation may always be improved by transferring stages from the bottom to the top section if $(L_T/V_T) > (V_B/L_B)$. This is not generally true (and is not really 'allowed' as it violates the assumption of optimal feed location). Second, although the formula gives the correct limiting value $S = \alpha^N$ for infinite reflux, it overestimates the value of S at lower reflux rates. This is not surprising since at low reflux rates a pinch zone develops around the feed.

Example Consider again the column with $N = 40$, $N_F = 21$, $\alpha = 1.5$, $z_L = 0.5$, $F = 1$, $D = 0.5$; $L_T = 2.706$. Exact calculations based on these data give $x_{HD} = x_{LB} = 0.01$ and $S = 9801$. On the other hand, the extended Fenske formula with $N_T = 20$ and $N_B = 20$ yields:

$$S = 1.5^{41} \times \frac{(2.706/3.206)^{20}}{(3.706/3.206)^{20}} = 16\,586\,000 \times \frac{0.34}{18.48} = 30\,774$$

corresponding to $x_{HD} = x_{LB} = 0.0057$. The error may seem large, but it is actually quite good for such a simple formula.

Optimal Feed Location

The optimal feed-stage location is at the intersection of the two operating lines in the McCabe-Thiele diagram. The corresponding optimal feed-stage composition (x_F, y_F) can be obtained by solving the following two equations: $z = qx_F + (1 - q)y_F$ and $y_F = \alpha x_F / (1 + (\alpha - 1)x_F)$. For $q = 1$ (liquid feed) we find $x_F = z$ and for $q = 0$ (vapour feed) we find $y_F = z$ (in the other cases we must solve a second-order equation).

There exists several simple short-cut formulas to estimate the feed point location. One may be derived from the Kremser equations given above. Divide the Kremser equation for the top by the one for the bottom and assume that the feed is optimally located to derive:

$$\frac{y_{H,F}}{x_{L,F}} = \frac{x_{H,D}}{x_{L,B}} \alpha^{(N_T - N_B)}$$

$$\times \frac{\left(\frac{L_T}{V_T}\right)^{N_T} \left[1 + \left(1 - \frac{L_T}{V_T}\right) \frac{(1 - a^{-N_T})}{(a - 1)}\right]}{\left(\frac{V_B}{L_B}\right)^{N_B} \left[1 + \left(1 - \frac{V_B}{L_B}\right) \frac{(1 - s^{-N_B})}{(s - 1)}\right]}$$

The last big term is close to 1 in most cases and can be neglected. Rewriting the expression in terms of the light component then gives Skogestad's short-cut formula for the feed stage location:

$$N_T - N_B = \frac{\ln \left(\left[\frac{(1 - y_F)}{x_F} \right] \left[\frac{x_B}{(1 - x_D)} \right] \right)}{\ln \alpha} \quad [36]$$

where y_F and x_F at the feed stage are obtained as explained above. The optimal feed-stage location counted from the bottom is then:

$$N_F = N_B + 1 = \frac{[N + 1 - (N_T - N_B)]}{2} \quad [37]$$

where N is the total number of stages in the column.

Summary for Continuous Binary Columns

With the help of a few of the above formulas it is possible to perform a column design in a matter of minutes by hand calculations. We will illustrate this with a simple example.

We want to design a column for separating a saturated vapour mixture of 80% nitrogen (L) and 20% oxygen (H) into a distillate product with 99% nitrogen and a bottoms product with 99.998% oxygen (mole fractions).

Component data Normal boiling points (at 1 atm): $T_{bL} = 77.4$ K, $T_{bH} = 90.2$ K, heat of vaporization at normal boiling points: 5.57 kJ mol⁻¹ (L) and 6.82 kJ mol⁻¹ (H).

The calculation procedure when applying the simple methods presented in this article can be done as shown in the following steps:

1. Relative volatility: The mixture is relatively ideal and we will assume constant relative volatility. The estimated relative volatility at 1 atm based on the boiling points is $\ln \alpha \approx (\Delta \bar{H}^{\text{vap}}/R\bar{T}_b) [(T_{bH} - T_{bL})/\bar{T}_b]$ where $\Delta \bar{H}^{\text{vap}} = \sqrt{5.57 \cdot 6.82} = 6.16$ kJ mol⁻¹, $\bar{T}_b = \sqrt{T_{bH} T_{bL}} = 83.6$ K and $T_H - T_L = 90.2 - 77.7 = 18.8$. This gives $(\Delta \bar{H}^{\text{vap}})/(R\bar{T}_b) = 8.87$ and we find $\alpha \approx 3.89$ (however, it is generally recommended to obtain α from experimental VLE data).
2. Product split: From the overall material balance we get $D/F = (z - x_B)/(x_D - x_B) = (0.8 - 0.00002)/(0.99 - 0.00002) = 0.808$.

3. Number of stages: The separation factor is $S = (0.99 \times 0.99998)/(0.01 \times 0.00002) = 4950000$, i.e. $\ln S = 15.4$. The minimum number of stages required for the separation is $N_{\min} = \ln S / \ln \alpha = 11.35$ and we select the actual number of stages as $N = 23$ ($\approx 2N_{\min}$).
4. Feed-stage location: With an optimal feed location we have at the feed stage ($q = 0$) that $y_F = z_F = 0.8$ and $x_F = y_F/(\alpha - (\alpha - 1)y_F) = 0.507$. Skogestad's approximate formula for the feed-stage location gives:

$$\begin{aligned} N_T - N_B &= \ln \left(\left[\frac{(1 - y_F)}{x_F} \right] \left[\frac{x_B}{(1 - x_D)} \right] \right) / (\ln \alpha) \\ &= \ln \left(\left[\frac{0.2}{0.507} \right] \times \left[\frac{0.00002}{0.01} \right] \right) / 1.358 \\ &= -5.27 \end{aligned}$$

corresponding to the feed stage $N_F = [N + 1 - (N_T - N_B)]/2 = (23 + 1 + 5.27)/2 = 14.6$.

5. Energy usage: The minimum energy usage for a vapour feed (assuming sharp separation) is $V_{\min}/F = 1/(\alpha - 1) = 1/2.89 = 0.346$. With the choice $N = 2N_{\min}$, the actual energy usage (V) is then typically about 10% above the minimum (V_{\min}), i.e. V/F is about 0.38.

This concludes the simple hand calculations. Note again that the number of stages depends directly on the product purity (although only logarithmically), whereas for well-designed columns (with a sufficient number of stages) the energy usage is only weakly dependent on the product purity.

Remark 1 The actual minimum energy usage is slightly lower since we do not have sharp separations. The recovery of the two components in the bottom product is $r_L = (x_{L,B}B)/(z_{FL}F) = 0.9596$ and $r_H = (x_{H,B}B)/(z_{FH}F) \approx 0$, so from the formulas given earlier the exact value for nonsharp separations is $V_{\min}/F = (0.9596 - 0.0 \times 3.89)/(3.89 - 1) = 0.332$.

Remark 2 For a liquid feed we would have to use more energy, and for a sharp separation:

$$V_{\min}/F = 1/(\alpha - 1) + D/F = 0.346 + 0.808 = 1.154$$

Remark 3 We can check the results with exact stage-by-stage calculations. With $N = 23$, $N_F = 15$ and $\alpha = 3.89$ (constant), we find $V/F = 0.374$, which is about 13% higher than $V_{\min} = 0.332$.

Remark 4 A simulation with more rigorous VLE computations, using the Soave-Redlich-Kwong (SRK) equation of state, has been carried out using the HYSYS (Hypnotech Ltd.) simulation package.

The result is a slightly lower vapour flow due to a higher relative volatility (α in the range 3.99–4.26 with an average of 4.14). More precisely, a simulation with $N = 23$, $N_F = 15$ gave $V/F = 0.291$, which is about 11% higher than the minimum value $V'_{\min} = 0.263$ found with a very large number of stages (increasing $N > 60$ did not give any significant energy reduction below V'_{\min}). The optimal feed stage (with $N = 23$) was indeed found to be $N_F = 15$.

Thus, the results from HYSYS confirm that a column design based on the very simple short-cut methods is very close to results from much more rigorous computations.

Multicomponent Distillation – Underwood's Methods

We present here the Underwood equations for multicomponent distillation with constant relative volatility and constant molar flows. The analysis is based on considering a two-product column with a single feed, but the usage can be extended to all kinds of column section interconnections.

It is important to note that adding more components does not give any additional degrees of freedom in operation. This implies that for an ordinary two-product distillation column we still have only two degrees of freedom, and thus we will only be able to specify two variables, e.g. one property for each product. Typically, we specify the purity (or recovery) of the light key in the top and of the heavy key in the bottom (the key components are defined as the components between which we are performing the split). The recoveries for all other components and the internal flows (L and V) will then be completely determined.

For a binary mixture with given products, as we increase the number of stages, there develops a pinch zone on both sides of the feed stage. For a multicomponent mixture, a feed region pinch zone only develops when all components distribute to both products, and the minimum energy operation is found for a particular set of product recoveries, sometimes denoted as the preferred split. If all components do not distribute, the pinch zones will develop away from the feed stage. Underwood's methods can be used in all these cases, and are especially useful for the case of infinite number of stages.

The Basic Underwood Equations

The net material transport (w_i) of component i upwards through a stage n is:

$$w_i = V_n y_{i,n} - L_{n+1} x_{i,n+1} \quad [38]$$

Note that w_i is always constant in each column section. We will assume constant molar flows ($L = L_n = L_{n-1}$ and $V = V_n = V_{n+1}$) and, assuming constant relative volatility, the VLE relationship is:

$$y_i = \frac{\alpha_i x_i}{\sum_i \alpha_i x_i} \quad \text{where } \alpha_i = \frac{(y_i/x_i)}{(y_r/x_r)} \quad [39]$$

We divide eqn [38] by V , multiply with the factor $\alpha_i/(\alpha_i - \phi)$, and take the sum over all components:

$$\frac{1}{V} \sum_i \frac{\alpha_i w_i}{(\alpha_i - \phi)} = \frac{\sum_i \frac{\alpha_i^2 x_{i,n}}{(\alpha_i - \phi)}}{\sum_i \alpha_i x_{i,n}} - \frac{L}{V} \sum_i \frac{\alpha_i x_{i,n+1}}{(\alpha_i - \phi)} \quad [40]$$

The parameter ϕ is free to choose, and the Underwood roots are defined as the values of ϕ which make the left-hand side of eqn [40] unity, i.e.:

$$V = \sum_i \frac{\alpha_i w_i}{(\alpha_i - \phi)} \quad [41]$$

The number of values ϕ satisfying this equation is equal to the number of components.

Most authors usually use a product composition or component recovery (r) in this definition, e.g. for the top (subscript T) section or the distillate product (subscript D):

$$w_i = w_{i,T} = w_{i,D} = D x_{i,D} = r_{i,D} z_i F \quad [42]$$

but we prefer to use w since it is more general. Note that use of the recovery is equivalent to using net component flow, but use of the product composition is only applicable when a single product stream is leaving the column. If we apply the product recovery, or the product composition, the defining equation for the top section becomes:

$$V_T = \sum_i \frac{\alpha_i r_{i,D} z_i F}{(\alpha_i - \phi)} = \sum_i \frac{\alpha_i x_{i,D}}{(\alpha_i - \phi)} D \quad [43]$$

Stage-to-Stage Calculations

With the definition of ϕ from eqn [41], eqn [40] can be simplified to:

$$\frac{L}{V} \sum_i \frac{\alpha_i x_{i,n+1}}{(\alpha_i - \phi)} = \frac{\phi \sum_i \frac{\alpha_i x_{i,n}}{(\alpha_i - \phi)}}{\sum_i \alpha_i x_{i,n}} \quad [44]$$

This equation will be valid for any of the Underwood roots, and if we assume constant molar flows and

divide an equation for ϕ_k with the one for ϕ_j , the following expression appears:

$$\left(\frac{\sum_i \frac{\alpha_i x_{i,n+m}}{(\alpha_i - \phi_j)}}{\sum_i \frac{\alpha_i x_{i,n}}{(\alpha_i - \phi_j)}} \right) = \left(\frac{\phi_k}{\phi_j} \right)^m \left(\frac{\sum_i \frac{\alpha_i x_{i,n}}{(\alpha_i - \phi_k)}}{\sum_i \frac{\alpha_i x_{i,n}}{(\alpha_i - \phi_j)}} \right) \quad [45]$$

and we note the similarities with the Fenske and Kremser equations derived earlier. This relates the composition on a stage (n) to a composition on another stage ($n+m$). The number of independent equations of this kind equals the number of Underwood roots minus 1 (since the number of equations of the type as in eqn [44] equals the number of Underwood roots), but in addition we also have $\sum x_i = 1$. Together, this is a linear equation system for computing $x_{i,n+m}$ when $x_{i,n}$ is known and the Underwood roots are computed from eqn [41].

Note that so far we have not discussed minimum reflux (or vapour flow rate), thus these equations hold for any vapour and reflux flow rates, provided that the roots are computed from the definition in eqn [41].

Some Properties of the Underwood Roots

Underwood showed a series of important properties of these roots for a two-product column with a reboiler and condenser. In this case all components flows upwards in the top section ($w_{i,T} \geq 0$), and downwards in the bottom section ($w_{i,B} \leq 0$). The mass balance yields: $w_{i,B} = w_{i,T} - w_{i,F}$ where $w_{i,F} = F z_i$. Underwood showed that in the top section (with N_c components) the roots (ϕ) obey:

$$\alpha_1 > \phi_1 > \alpha_2 > \phi_3 > \alpha_3 > \dots > \alpha_{N_c} > \phi_{N_c}.$$

And in the bottom section (where $w_{i,n} = w_{i,B} \leq 0$) in general we have a different set of roots denoted (ψ) computed from $V_B = \sum_i [\alpha_i w_{i,B}/(\alpha_i - \psi)] = \sum_i [\alpha_i (-r_{i,B} z_i)/(\alpha_i - \psi)] = \sum_i [\alpha_i (-(1-r_{i,D})) z_i/(\alpha_i - \psi)]$ which obey:

$$\psi_1 > \alpha_1 > \psi_2 > \alpha_2 > \psi_3 > \alpha_3 > \dots > \psi_{N_c} > \alpha_{N_c}.$$

Note that the smallest root in the top section is smaller than the smallest relative volatility, and the largest root in the bottom section is larger than the largest volatility. It is easy to see from the defining equations that $V_T \rightarrow \infty \Rightarrow \phi_i \rightarrow \alpha_i$ and similarly $V_B \rightarrow \infty \Rightarrow \psi_i \rightarrow \alpha_i$.

When the vapour flow is reduced, the roots in the top section will decrease, while the roots in the bottom section will increase, but interestingly Underwood showed that $\phi_i \geq \psi_{i+1}$. A very important result

by Underwood is that for an infinite number of stages $V \rightarrow V_{\min} \Rightarrow \phi_i \rightarrow \psi_{i+1}$.

Then, at minimum reflux, the Underwood roots for the top (ϕ) and bottom (ψ) sections coincide. Thus, if we denote the common roots (θ), and recall that $V_T - V_B = (1 - q)F$, we obtain the following equation for the common roots (θ) by subtracting the defining equations for the top and bottom sections:

$$(1 - q) = \sum_i \frac{\alpha_i z_i}{(\alpha_i - \theta)} \quad [46]$$

We call this expression the feed equation since only the feed properties (q and z) appear. Note that this is not the equation which defines the Underwood roots and the solutions (θ) apply as roots of the defining equations only for minimum reflux conditions ($N = \infty$). The feed equation has N_c roots (but one of these is not a common root) and the $N_c - 1$ common roots obey: $\alpha_1 > \theta_1 > \alpha_2 > \theta_2 > \dots > \theta_{N_c-1} > \alpha_{N_c}$. Solution of the feed equation gives us the possible common roots, but all pairs of roots (ϕ_i and ψ_{i+1}) for the top and bottom section do not necessarily coincide for an arbitrary operating condition. We illustrate this with the following example.

Example Assume we start with a given product split (D/F) and a large vapour flow (V/F). Then only one component i (with relative volatility α_i) can be distributed to both products. No roots are common. Then we gradually reduce V/F until a second component j (this has to be a component $j = i + 1$ or $j = i - 1$) becomes distributed, e.g. for $j = i + 1$ one set of roots will coincide: $\phi_i = \psi_{i+1} = \theta_i$, while the others do not. As we reduce V/F further, more components become distributed and the corresponding roots will coincide, until all components are distributed to both products, and then all the $N_c - 1$ roots from the feed equation are also roots for the top and bottom sections.

An important property of the Underwood roots is that the value of a pair of roots which coincide (e.g. when $\phi_i = \psi_{i+1} = \theta_i$) will not change, even if only one, two or all pairs coincide. Thus all the possible common roots are found by solving the feed equation once.

Minimum Energy – Infinite Number of Stages

When we go to the limiting case of infinite number of stages, Underwood's equations become very useful. The equations can be used to compute the minimum energy requirement for any feasible multicomponent separation.

Let us consider two cases: first we want to compute the minimum energy for a sharp split between two adjacent key components j and $j + 1$ ($r_{j,D} = 1$ and

$r_{j+1,D} = 0$). The procedure is then simply:

1. Compute the common root (θ_j) for which $\alpha_j > \theta_j > \alpha_{j+1}$ from the feed equation: $(1 - q) = \sum_i [a_i z_i / (a_i - \theta)]$
2. Compute the minimum energy by applying θ_j to the definition equation:

$$V_{T,\min}/F = \sum_{i=1}^j a_i z_i / (a_i - \theta_j).$$

Note that the recoveries

$$r_{i,D} = \begin{cases} 1 & \text{for } i \leq j \\ 0 & \text{for } i > j \end{cases}$$

For example we can derive King's expressions for minimum reflux for a binary feed ($z_L = z$, $z_H = (1 - z)$, $\alpha_L = \alpha$, $\alpha_H = 1$, and liquid feed ($q = 1$)). Consider the case with liquid feed ($q = 1$). We find the single common root from the feed equation: $\theta = \alpha / (1 + (\alpha - 1)z)$, (observe $\alpha \geq \theta \geq 1$, as expected). The minimum reflux expression appears as we use the defining equation with the common root:

$$\frac{L_{T,\min}}{F} = \frac{V_{T,\min}}{F} - \frac{D}{F} = \sum_i \frac{\theta r_{i,D} z_i}{(\alpha_i - \theta)} = \frac{\theta r_{L,D} z}{\alpha - \theta} + \frac{\theta r_{H,D} (1 - z)}{1 - \theta}$$

and when we substitute for θ and simplify, we obtain King's expression: $L_{T,\min}/F = (r_{L,D} - \alpha r_{H,D}) / (\alpha - 1)$. Another interesting case is minimum energy operation when we consider sharp split only between the most heavy and most light components, while all the intermediates are distributed to both products. This case is also denoted the preferred split, and in this case there will be a pinch region on both sides of the feed stage. The procedure is:

1. Compute all the $N_c - 1$ common roots (θ) from the feed equation.
2. Set $r_{1,D} = 1$ and $r_{N_c,D} = 0$ and solve the following linear equation set ($N_c - 1$ equations) with respect to $[V^T, r_{2,D}, r_{3,D}, \dots, r_{N_c-1,D}]$ ($N_c - 1$ variables):

$$V^T = \sum_{i=1}^{N_c} \frac{a_i r_{i,D} z_i}{(a_i - \theta_i)} : \quad V^T = \sum_{i=1}^{N_c} \frac{a_i r_{i,D} z_i}{(a_i - \theta_{N_c-1})} \quad [47]$$

Note that, in this case, when we regard the most heavy and light components as the keys, and all the intermediates are distributed to both products, King's very simple expression will also give the correct

minimum reflux for a multicomponent mixture (for $q = 1$ or $q = 0$). The reason is that the pinch then occurs at the feed stage. In general, the values computed by King's expression give a (conservative) upper bound when applied directly to multicomponent mixtures. An interesting result which can be seen from King's formula is that the minimum reflux at the preferred split (for $q = 1$) is independent of the feed composition and also independent of the relative volatilities of the intermediates.

However, with the Underwood method, we also obtain the distribution of the intermediates, and it is easy to handle any liquid fraction (q) in the feed.

The procedure for an arbitrary feasible product recovery specification is similar to the preferred split case, but then we must only apply the Underwood roots (and corresponding equations) with values between the relative volatilities of the distributing components at the limit of being distributed. In cases where not all components distribute, King's minimum reflux expression cannot be trusted directly, but it gives a (conservative) upper bound.

Figure 9 shows an example of how the components are distributed to the products for a ternary (ABC) mixture. We chose the overhead vapour flow ($V = V_T$) and the distillate product flow ($D = V - L$) as the two degrees of freedom. The straight lines,

which are at the boundaries when a component is at the limit of appearing/disappearing (distribute/not distribute) in one of the products, can be computed directly by Underwood's method. Note that the two peaks (P_{AB} and P_{BC}) give us the minimum vapour flow for a sharp split between A/B and B/C. The point P_{AC} , however, is at the minimum vapour flow for a sharp A/C split and this occurs for a specific distribution of the intermediate B, known as the preferred split.

King's minimum reflux expression is only valid in the triangle below the preferred split, while the Underwood equations can reveal all component recoveries for all possible operating points. (The shaded area is not feasible since reflux and vapour flow rates have to be positive ($V > D$, $V > (1 - q)F$).

Further Discussion of Specific Issues

The Energy Balance and the Assumption of Constant Molar Flows

All the calculations in this article are based on the assumption of constant molar flows in a section, i.e. $V_n = V_{n-1} = V$ and $L_n = L_{n+1} = L$. This is a very common simplification in distillation computations, and we shall use the energy balance to see when we can justify it. The energy balance is similar to the

Figure 9 Regions of distributing feed components as a function of V and D for a feed mixture with three components: ABC. P_{ij} represents minimum energy for sharp split between components i and j . For large vapour flow (above the top sawtooth), only one component distributes. In the triangle below P_{AC} , all components distribute.

mass balance, but now we use the molar enthalpy (h) of the streams instead of composition. The enthalpy is computed for the actual mixture and will be a function of composition in addition to temperature (or pressure). At steady state the energy balance around stage n becomes:

$$L_n h_{L,n} - V_{n-1} h_{V,n-1} = L_{n+1} h_{L,n+1} - V_n h_{V,n} \quad [48]$$

Combining this energy balance with the overall material balance on a stage ($V_{n-1} - L_n = V_n - L_{n+1} = W$ where W is the net total molar flow through a section, i.e. $W = D$ in the top section and $W = B$ in the bottom section) yields:

$$V_n = V_{n-1} \frac{h_{V,n-1} - h_{L,n}}{h_{V,n} - h_{L,n+1}} + W \frac{h_{L,n} - h_{L,n+1}}{h_{V,n} - h_{L,n+1}} \quad [49]$$

From this expression we observe how the vapour flow will vary though a section due to variations in heat of vaporization and molar enthalpy from stage to stage.

We will now show one way of deriving the constant molar flow assumption:

1. Choose the reference state (where $h = 0$) for each pure component as saturated liquid at a reference pressure. (This means that each component has a different reference temperature, namely its boiling point (T_{bpi}) at the reference pressure.)
2. Assume that the column pressure is constant and equal to the reference pressure.
3. Neglect any heat of mixing such that

$$h_{L,n} = \sum_i x_{i,n} c_{PLi} (T_n - T_{bpi}).$$

4. Assume that all components have the same molar heat capacity, c_{PL} .
5. Assume that the stage temperature can be approximated by $T_n = \sum_i x_{i,n} T_{bpi}$. These assumptions give $h_{L,n} = 0$ on all stages and eqn [49] for change in boil-up is reduced to:

$$V_n = V_{n-1} \frac{h_{V,n-1}}{h_{V,n}}$$

6. The molar enthalpy in the vapour phase is given as: $h_{V,n} = \sum_i x_{i,n} \Delta H_{bpi}^{vap} + \sum_i x_{i,n} c_{PV,i} (T_n - T_{bpi})$ where ΔH_{bpi}^{vap} is the heat of vaporization for the pure component at its reference boiling temperature (T_{bpi}).
7. We assume that c_{PV} is equal for all components, and then the second summation term above will become zero, and we have: $h_{V,n} = \sum_i x_{i,n} \Delta H_{bpi}^{vap}$.
8. Then if $\Delta H_{bpi}^{vap} = \Delta H^{vap}$ is equal for all components we get $h_{V,n} = h_{V,n-1} = \Delta H^{vap}$, and thereby constant molar flows: $V_n = V_{n-1}$ and also $L_n = L_{n+1}$.

At first glance, these assumptions may seem restrictive, but the assumption of constant molar flows actually holds well for many industrial mixtures.

In a binary column where the last assumption about equal ΔH_{bpi}^{vap} is not fulfilled, a good estimate of the change in molar flows from the bottom (stage 1) to the top (stage N), due to this effect for a case with saturated liquid feed ($q = 1$) and close to pure products, is given by: $V_N/V_1 \approx \Delta H_H^{vap}/\Delta H_L^{vap}$, where the molar heat of vaporization is taken at the boiling point temperatures for the heavy (H) and light (L) components respectively.

Recall that the temperature dependency of the relative volatility is related to different heat of vaporization also, thus the assumptions of constant molar flows and constant relative volatility are closely related.

Calculation of Temperature when Using Relative Volatilities

It may seem that we have lost the pressure and temperature in the equilibrium equation when we introduced the relative volatility. However, this is not the case since the vapour pressure for every pure component is a direct function of temperature, thus it is also the relative volatility. From the relationship $P = \sum p_i = \sum x_i p_i^o(T)$ we derive:

$$P = p_r^o(T) \sum_i x_i \alpha_i \quad [50]$$

Remember that only one of P or T can be specified when the mole fractions are specified. If composition and pressure are known, a rigorous solution of the temperature is found by solving the nonlinear equation:

$$P = \sum x_i p_i^o(T) \quad [51]$$

However, if we use the pure component boiling points (T_{bi}), a crude and simple estimate can be computed as:

$$T \approx \sum x_i T_{bi} \quad [52]$$

For ideal mixtures, this usually gives an estimate which is a bit higher than the real temperature; however, a similar approximation may be done by using the vapour composition (y), which will usually give a lower temperature estimate. This leads to a good estimate when we use the average of x and y , i.e.:

$$T \approx \sum \left(\frac{x_i + y_i}{2} \right) T_{bi} \quad [53]$$

Figure 10 Temperature profile for the example shown in Figure 7 (continuous line) compared with various linear boiling point approximations.

Alternatively, if we are using relative volatilities we may find the temperature via the vapour pressure of the reference component. If we use the Antoine equation, then we have an explicit equation:

$$T \approx \frac{B_r}{\log p_r^\circ - A_r} + C_r \quad \text{where } p_r^\circ = P / \sum_i x_i \alpha_i \quad [54]$$

This last expression is a very good approximation to a solution of the nonlinear eqn [51]. An illustration of how the different approximations behave is shown in Figure 10. For that particular case (a fairly ideal mixture), eqns [53] and [54] almost coincide.

In a rigorous simulation of a distillation column, the mass and energy balances and the VLE have to be solved simultaneously for all stages. The temperature is then often used as an iteration parameter in order to compute the vapour pressures in VLE computations and in the enthalpy computations of the energy balance.

Discussion and Caution

Most of the methods presented in this article are based on ideal mixtures and simplifying assumptions about constant molar flows and constant relative volatility. Thus there are many separation cases for nonideal systems where these methods cannot be applied directly.

However, if we are aware of the most important shortcomings, we may still use these simple methods for short-cut calculations, for example, to gain insight or check more detailed calculations.

Tray Columns: Design

Distillation has remained an important separation technology for the chemical process industries. In 1997 it was reported in the journal *Chemical Engineering* that about 95% of all worldwide separation processes use this technology. In the USA alone, some 40 000 distillation columns represent a capital investment of about US \$8 billion. They consume the energy equivalent of approximately 1 billion barrels of crude oil per day. Such columns are used in refineries, petrochemical plants, gas processing plants and organic chemical plants to purify natural gas, improve gasoline, produce petrochemicals and organic products, recover pollutant species, etc.

Distillation can be carried out in a tray or a packed column. The major considerations involved in the choice of the column type are operating pressure and design reliability. As pressure increases, tray columns become more efficient for mass transfer and can often tolerate the pressure drop across the trays. The design procedure for the large diameter tray column is also more reliable than that for the packed column. Thus, trays are usually selected for large pressurized column applications.

Distillation trays can be classified as:

1. cross-flow trays with downcomers (see **Figure 1A**);
2. countercurrent trays without downcomers (also known as dual-flow trays) (see **Figure 1B**).

The dual-flow tray allows the gas and liquid to pass through the same tray openings. This results in a limited operating range because the dispersion height is very sensitive to the gas/liquid flow rates. In general, dual-flow trays are employed only in cases where high capacity or high resistance to fouling are required. However, because of its narrow operating range, the market share is small and such trays will not be discussed further.

The cross-flow tray utilizes a weir on the downcomer to control the spray height on the tray, and thus provides a stable gas-liquid dispersion over a wide range of gas/liquid flows. A tray is the combination of a tray deck, where froth is generated to provide vapour-liquid contact, and a downcomer, where the vapour-liquid mixture is separated. The bulk of the vapour rises from the aerated liquid through the vapour disengagement space to the tray above. However, the passage of the liquid from the

top to the bottom of the column occurs mainly via downcomers.

There are three types of cross-flow trays: (1) sieve, (2) valve and (3) bubble cap. Among them, sieve trays offer high capacity and efficiency, low pressure drop, ease of cleaning, and low capital cost, but smaller turndown ratio. Although the design procedure is similar for all three types of trays, only sieve tray performance data are readily available in the public domain. The valve and bubble cap designs are often protected by patents, and thus the performance data are supplied by the vendors. This article describes the procedure for designing an optimum sieve tray. A similar procedure can be applied in principle to the valve and bubble cap trays, provided critical performance data are available.

The cost of a tray column is determined by two factors:

1. column diameter, which determines the throughput;

Figure 1 (A) Sieve tray with downcomer in a 30 cm diameter column. (B) Dual-flow tray in a 30 cm diameter column.

2. column height, which delivers the number of equilibrium stages required for the separation.

The minimum cost is generally achieved when the column volume is minimized. The final selection of the tray design is based on the combined cost of the column shell, internals and installation.

It should be noted that the fraction of the cross-sectional area available for vapour-liquid disengagement decreases when the downcomer area is increased. Thus, optimum design of the tray involves a balance between the tray area and the downcomer area (i.e. the capacity for the tray deck should match the capacity of the downcomer). The correlations for sizing trays are implicit in column diameter, tray spacing and tray geometry, thus requiring trial-and-error calculations to arrive at the final selection.

Characteristics of Tray Operation

Typical tray layout is shown in Figure 2, and tray operation is shown in Figure 3. High speed photography of a large operating tray indicates that the vapour erupts through the liquid sporadically. The holes that are not erupting do not weep appreciably at a vapour rate above the weep point, although the supporting of the liquid by the vapour is not absolutely complete. The interaction of vapour and liquid on a properly designed tray results in a highly turbulent two-phase mixture of a high specific interfacial area with net

liquid movement in a crossflow direction to the rising vapour stream. The aerated liquid may be either liquid-continuous (froth) at relatively low vapour velocities or vapour-continuous (spray) at high vapour velocities.

The maximum capacity of a sieve tray is reached when the tray is flooded. This may be due to excessive spraying (entrainment) taking place in the intertray space or the froth in the downcomer backing-up to reach the top of the outlet weir. The onset of flooding is accompanied by a sharp increase in tray pressure and a sharp decrease in tray efficiency.

As vapour rates decrease to the point that the vapour flow cannot totally support the liquid on the tray, some liquid will weep through the holes. If the weepage is so severe that no liquid flows over the outlet weir, the tray cannot operate stably under these dumping conditions. The minimum capacity of the tray is normally reached when moderate weepage is encountered. Ideally, a sieve tray should operate in the shaded area shown in Figure 4 to ensure proper operation.

Tray efficiency can be divided into two components:

1. point efficiency as determined by the vertical flow of vapour through the froth;
2. tray efficiency enhancement by the crossflow of liquid.

The physical properties of the vapour-liquid mixture determine the point efficiency, although froth height, which influences the gas residence time, also has a significant effect, especially for low efficiency systems. Liquid flow pathlength determines the liquid residence time and the extent of crossflow tray efficiency enhancement. Entrainment and weeping depress tray efficiency by disrupting the concentration profile in the column. The froth height and the liquid flow path are two parameters that are optimized to give maximum tray efficiency. Other geometric variables, such as open hole area, hole diameter and downcomer arrangement, also affect tray hydraulics and efficiency. The goal for a tray design is to reach maximum tray efficiency without compromising hydraulic stability.

The steps required for tray column design are shown in Figure 5; a detailed discussion of each step is given below.

Input Data

Once sieve trays are selected for a given application, the input data that are required in the design calculations include density, viscosity, surface tension, diffusivity and flow rate of the liquid stream, as

Figure 2 Tray layouts.

Figure 3 Tray operation schematic diagram.

well as density, diffusivity and flow rate of the vapour stream. This information can be obtained by performing tray-to-tray distillation calculations; several commercial computer packages are available for this purpose (e.g. PRO II, ASPEN PLUS, HYSIM).

As the physical properties and the vapour and liquid flow rates vary throughout a given column, it is difficult to provide a single design for the entire column. Instead, the column is divided into a number of sections. Within each section, trays are designed with the same layout. Normally the section is a set of trays bounded by two column penetrations (feed and/or drawoff). Tray design calculations should be performed to ensure that trays at the top and bottom of the section meet the design requirements.

Preliminary Specifications

Tray Spacing

Tray spacing is set by maintenance requirements, and also by support structure design in large-diameter columns. Sufficient crawl space must be provided for tray cleaning and repair. From these considerations, the minimum tray spacing is about 12 in (30 cm) for column diameter less than 5 ft, and (150 cm) and 18 in (45 cm) for a column diameter greater than 10 ft (300 cm). In general, it is best to keep tray spacing to a minimum, which is often the most economical.

Downcomer Area

The downcomer area at the top is sized such that the velocity of the ascending vapour bubbles exceeds the downflow velocity of the liquid. The size is related to

the stability of the froth in the downcomer and determined by the residence time required for achieving the separation of the two-phase mixture. For non-foaming systems, such as lower alcohols, a residence time of 3 s is sufficient, whereas for extremely high foaming systems such as caustic regenerators, 9 s is required.

To prevent the liquid coming off the bubbling area from splashing against the column wall, the minimum downcomer width is 5 in (12.7 cm). Also, the minimum side chord length should be 60% of the column diameter. This is required to maintain good liquid distribution on the tray.

Since the separation of the vapour-liquid mixture is complete at the bottom of the downcomer, a sloped downcomer can be used to maximize the active tray area. In this case, the downcomer area at the bottom should be about 60% of that at the top.

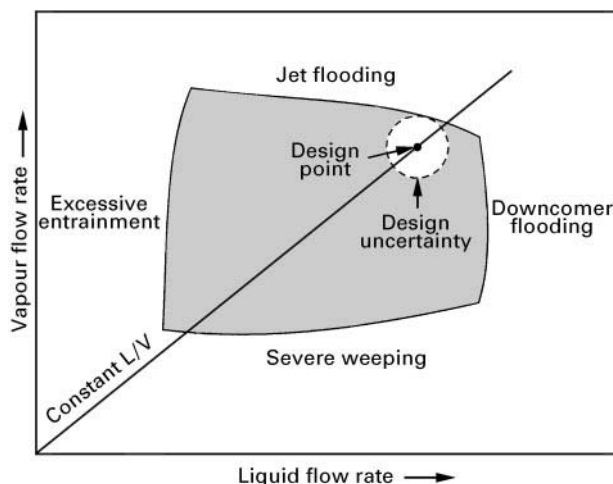

Figure 4 Sieve tray performance diagram.

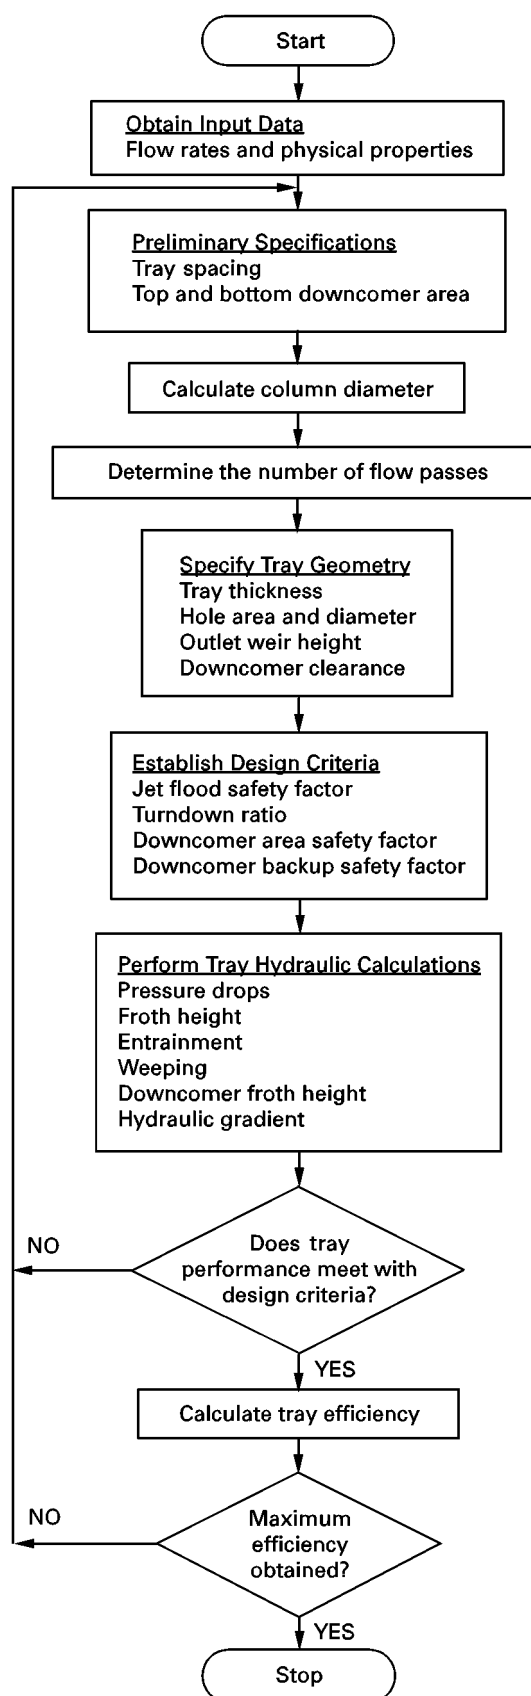

Figure 5 Sieve tray design procedure.

It should be noted that the downcomer area occupies only a small fraction of the cross-sectional area. Thus, a small overdesign does not result in a significant economic penalty.

Column Diameter

The column diameter can be calculated once the tray spacing and downcomer area have been specified. The Fair correlation, based on the Souders and Brown criterion, is recommended by most designers. The vapour flooding velocity can be calculated from eqn [1].

$$U_{N,f} = C_{SB} \left(\frac{\rho_L - \rho_V}{\rho_V} \right)^{0.5} \left(\frac{\sigma_L}{20} \right)^{0.2} \quad [1]$$

In eqn [1] C_{SB} is the Souders–Brown coefficient, ρ_L and σ_L (dyne cm^{-1}) are liquid density and surface tension, respectively, and ρ_V is the vapour density in the same units as ρ_L . $U_{N,f}$ is based on the net area, $A_N(\text{ft}^2)$, which is the active area plus one downcomer area. The unit for $U_{N,f}$ is ft s^{-1} . The most popular empirical formula for calculating C_{SB} is given in eqn [2].

$$\begin{aligned} C_{SB}(\text{ft s}^{-1}) = & 0.04232 + 0.1674 T_s \\ & + (0.0063 - 0.2686 T_s) F_{IV} \\ & + (0.1448 T_s - 0.008) F_{IV}^2 \end{aligned} \quad [2]$$

In this equation $F_{IV} = (L/V)(\rho_V/\rho_L)^{0.5}$, T_s is tray spacing in feet, and L and V are mass flow rates of the liquid and vapour. The C_{SB} is valid for trays with a fractional hole area greater than 10%. For areas of 8% and 6%, C_{SB} should be multiplied by 0.9 and 0.8, respectively.

Knowing $U_{N,f}$ and the total vapour flow rate, the column diameter can be calculated by assuming that the column will be operated at a lower vapour velocity, say 80% of the flood point.

Number of Flow Passes

The number of flow passes is set to allow the tray to operate at a weir loading that does not result in excessive weir crest. The weir loading can be calculated once the column diameter and the downcomer area are determined. The optimum weir loading is 4–6 US gallons per minute and the maximum loading is about 20. Downcomer choking, which causes liquid build-up on the tray, may occur if the maximum value is exceeded. Increasing the number of flow passes provides a solution to this problem (see Figure 2). However, shorter liquid flow path and possible maldistribution of liquid and vapour streams in multipass trays may result in lower tray efficiency.

As a rule of thumb, the liquid and vapour handling capacity are a direct function of weir loading and column area, respectively. Since weir length and column area are proportional to column diameter and diameter squared, respectively, the use of multipass trays is often necessary for large-diameter columns.

Tray Geometry

Tray geometry should be chosen so that hydraulic and efficiency calculations can be performed to arrive at the optimum design. The following parameters must be specified for tray design calculations.

Tray Thickness

The choice of material for the fabrication of trays is dependent mainly on the corrosion properties of the process fluids. In general, tray thickness is about gauge 10 (0.134 in; 3.40 mm) for carbon steel and gauge 12 (0.109 in; 2.77 mm) for stainless steel. For economic reasons the holes are punched, which dictates that the thickness must be less than the hole diameter.

Hole Diameter

Small holes with a diameter in the range of $\frac{3}{16}$ to $\frac{1}{4}$ in (4.76–6.35 mm) give better hydraulic and mass transfer performance than the large ones in the range of $\frac{1}{2}$ to $\frac{3}{4}$ in (12.7–19.0 mm). However, large-hole trays are cheaper and show more resistance to fouling. Choose the hole size according to design requirements.

Hole Area

The hole area is normally in the range of 5–16% of the bubbling area. Lower hole area allows the tray to operate at higher efficiency and turndown ratio, but at the expense of higher pressure drop. Since the operating pressure of the column dictates the maximum allowable pressure drop, the hole area is selected according to the type of service. Recommended values are 5–10% for pressure and 10–16% for vacuum operations.

Hole areas below 5% are not used because the distance between holes becomes excessive and liquid channelling may occur. However, the distance can also be adjusted by changing the hole diameter. In general, the hole pitch should not be larger than 2.5 in (6.35 cm). On the other hand, if the hole areas are greater than 16%, significant weeping and entrainment may coexist and the design equations may not apply under these conditions.

Weir Design

Outlet weirs are used to control the froth height on the tray. For most trays, the outlet weir height is about 1–4 in (2.5–10 cm) and the downcomer clearance, where the liquid is discharged from the bottom of the downcomer onto the tray below, should be 0.5 in (1.25 cm) smaller than the outlet weir height to ensure a positive downcomer seal.

From the above discussion, it may be concluded that the object of tray design is to obtain the optimum combination of the following parameters:

1. column diameter
2. tray spacing
3. top and bottom downcomer area
4. hole diameter and hole area
5. outlet weir height and downcomer clearance.

Design Criteria

The trays should be designed for maximum throughput. However, owing to inaccuracies in the design equations and fluctuation of process conditions (e.g. flow rates, temperature and pressure), safety factors are needed to ensure stable column operation at all times (see Figure 4).

Jet Flood Safety Factor

The jet flood safety factor (JFSF) is defined as the ratio of vapour velocity required to entrain the entire liquid flow (U_{\max}) to the operating velocity (U_{op}). It is a useful measure of entrainment and hydraulic stability. The typical JFSF value is 1.2.

Turndown Ratio

For various reasons, the column may be operated at a reduced throughput. Weeping is encountered if the vapour velocity can no longer support the liquid on the tray. Although flow dynamics permit stable operation as long as dumping is avoided, tray efficiency suffers because weeping reduces the vapour–liquid contact. The turndown ratio is the ratio of the design vapour flow rate to the flow rate that permits some weeping without seriously affecting the tray efficiency. Recommended weepages at turndown conditions for vacuum and pressure operations are 3% and 7%, respectively.

Downcomer Area Safety Factor (DCASF) and Downcomer Backup Safety Factor (DCBUSF)

The liquid handling capacity of a tray is determined by downcomer design and tray spacing. The DCASF determines the approach of the top downcomer area

to the minimum area to the minimum area required for vapour–liquid disengagement. The DCBUSF determines the approach of the downcomer froth height to the downcomer depth (= tray spacing + outlet weir height). Safety factors in the range of 1.5–2.0 are recommended.

Pressure Drop

The pressure drop across an operating tray should be specified if it affects the number of equilibrium stage requirements for the separation. This is often the case for vacuum applications. Stable operation can be obtained at a pressure drop of 1–3 in (2.5–7.6 cm) of liquid per tray for vacuum and 2–5 in (5.1–12.7 cm) for pressure operations.

Design Calculations

Tray Hydraulics

The hydraulic performance of a sieve tray for a given layout may be calculated using the methods presented in 'Distillation/Tray Columns: Performance'.

Tray Efficiency

Tray efficiency is a strong function of the physical properties of the vapour and liquid streams. It is also affected, to a lesser extent, by the flow rates and tray layout. In the latter case, only hole diameter, hole area and weir height have a small influence on the tray efficiency. The optimum design, which gives the maximum number of equilibrium stages in a column, is often obtained at minimum tray spacing and minimum number of flow paths that satisfy the hydraulic design criteria.

Conclusions

A well-designed tray should be economical while meeting all process design requirements. Economic

considerations suggest that it is best to use the smallest column diameter and height that satisfy the process requirements within reasonable safety allowances. Process requirements include accommodation of the expected liquid and vapour flow ranges and the optimization of tray efficiency.

Tray Columns: Performance

K. Nandakumar and K. T. Chuang, University of Alberta, Edmonton, Alberta, Canada

Copyright © 2000 Academic Press

Introduction

As pointed out in the article entitled distillation tray columns: design, a sieve tray is designed with a num-

ber of objectives in mind. They include: (i) achieving high efficiency of contact between the liquid and the vapour so that the phases leaving a tray are as close to equilibrium conditions as possible; (ii) balancing the tray deck area provided for vapour/liquid contact with the downcomer area provided for disengagement of the two phases so that neither limits the capacity of the column to process large amounts of feed; and (iii) avoiding detrimental operating

conditions in the column such as *weeping*, *flooding* or high vapour *entrainment*.

Numerous geometrical factors have to be selected by the designer such as: (i) column diameter; (ii) tray spacing; (iii) top and bottom downcomer area; (iv) number of flow passes; (v) hole diameter and density; (vi) tray thickness; and (vii) weir design. This is a highly empirical process which depends on empirical design equations that describe the tray hydraulics and rule-of-thumb guidelines that have evolved over several decades of operating experience. Thus, the design of sieve tray columns has remained an art, although commercial process simulation software packages such as ASPEN, PRO II, HYSIM, etc., are trying to codify these procedures into their design packages. The conceptual steps in the design procedure together with the rule-of-thumb guidelines have been presented in the Tray Columns: Design article. Since frequent reference will be made to that article, we will henceforth refer to it simply as Part I.

In contrast, the performance analysis problem is relatively more scientific, in the sense that a series of well-defined steps leads to the estimation of the Murphree tray efficiency, the *column efficiency* and the *actual number of trays*. The overall column efficiency, E_o , is defined as:

$$E_o = \frac{N_{\text{equilibrium}}}{N_{\text{actual}}} \quad [1]$$

where $N_{\text{equilibrium}}$ is obtained from stagewise equilibrium design calculations. Performance evaluation boils down to estimating E_o so that the actual number of trays, N_{actual} , can be determined. The overall column efficiency, E_o , is related to the Murphree tray efficiency, E_{MV} , through the Lewis relationship (assuming constant slopes of equilibrium and operating lines), given by:

$$E_o = \frac{\ln [1 + E_{MV}(\lambda - 1)]}{\ln \lambda}$$

where $\lambda = mG/L$ is the separation factor, m is the slope of the equilibrium line, and (G, L) are the vapour and liquid flow rates in kmol s^{-1} . Thus the Murphree tray efficiency, E_{MV} , must be estimated in order to determine the column efficiency. The Murphree tray efficiency is defined to provide a measure of departure from the assumption of *ideal equilibrium tray* that is used to determine the number of *ideal stages* required to achieve a given separation. It is defined as:

$$E_{MV} = \frac{y_n - y_{n-1}}{y_n^* - y_{n-1}} \quad [2]$$

Figure 1 (A) Murphree tray efficiency. (B) Head in the downcomer.

Figure 1A illustrates various compositions. y_n is the actual composition of the vapour stream leaving tray n , while y_n^* is the composition that is in equilibrium with the exit liquid stream.

These two compositions would be the same, if and only if the condition of *ideal equilibrium tray* is satisfied. Since it is never satisfied in practice, it is important to be able to predict the tray efficiency. In fact, the compositions are not even uniform across the tray deck. Hence the above definition is applied at a local point on the tray and the point efficiency is integrated with the *variations in flow conditions* to predict a tray efficiency. The relationship between the inputs and the sequence of calculations is shown in Figure 2.

In Figure 2 the *point efficiency* is a function of local flow conditions such as local mass transfer coefficients in the liquid and vapour phases. The *dry Murphree* tray efficiency incorporates the effects of liquid and vapour distribution on the *point efficiency*, while the *wet Murphree* tray efficiency incorporates the additional effects of entrainment and weeping.

Figure 2 Steps in performance evaluation.

The tray efficiency, E_{MV} , clearly depends on: (i) the geometrical design parameters chosen as outlined in Part I; (ii) the physical properties of the system such as density, viscosity, surface tension, etc.; and (iii) the operating conditions like the vapour/liquid flow rates.

Having selected the design parameters identified in Part I, the objective of the performance analysis step is to predict: (i) the tray hydraulics (including the pressure drop, the flow regime, the froth density, the entrainment and weeping factors); (ii) the point efficiency; (iii) the Murphree tray efficiency; and (iv) the column efficiency. In the initial stages of designing a *new tray column*, there is feedback between the design and performance analysis steps to arrive at a set of optimal design parameters, as outlined in the flow chart (Figure 5 of part I). But the performance analysis steps to be outlined in this part, are also useful in analysing the performance of an *existing tray column*, although the opportunity to pick optimal design conditions is not present as one is forced to deal with an existing tray.

An excellent summary of the equations used to study the performance of a sieve tray column can be found in Zuiderweg (1982), Lockett (1986) and Kister (1992) (see Further Reading). The detailed steps involved in the performance analysis include: (i) the pressure drop prediction; (ii) froth height and density calculations; (iii) point efficiency prediction; and (iv) tray efficiency prediction. The inputs required are: (i) tray geometry; (ii) physical properties; and (iii) flow conditions.

Steps in Performance Analysis

Pressure Drop Calculation in Vapour Phase

The pressure drop in the vapour phase across a sieve tray is modelled as (Zuiderweg, 1982):

$$\Delta P = \Delta P_{\text{dry}} + \rho_l g h_l \quad [3]$$

where the dry pressure drop is given by:

$$\Delta P_{\text{dry}} = \frac{1}{2} \rho_G \left(\frac{u_{g,h}}{C_D} \right)^2 \quad [4]$$

Here, g is the acceleration due to gravity, h_l is the liquid height or hold-up in metres, $u_{g,h}$ is the vapour velocity in the hole in metres per second, C_D is the drag coefficient, and (ρ_G, ρ_l) are the densities of the vapour and liquid, respectively. The second term in eqn [3] represents the static head due to the liquid hold-up on the tray. Hence the liquid height, h_l must be predicted from correlations that depend on the

weir geometry. One such equation that predicts the liquid height is given by:

$$h_l = 0.6 H_w^{0.5} p^{0.25} (FP/b)^{0.25} \quad 25 \text{ mm} < H_w < 100 \text{ mm} \quad [5]$$

Here, H_w is the weir height in metres, p is the pitch of the holes in the sieve plate in metres, $FP = (u_l/u_g) \sqrt{(\rho_l/\rho_g)}$ is the flow parameter, b is the weir length per unit bubbling area in metres⁻¹.

The discharge coefficient, C_D in eqn [4] is a function of the flow conditions near a hole. It is in fact dependent on the liquid present on the tray. It is correlated by:

$$C_D = 0.7 \left[1 - 0.14 \left(\frac{g h_l \rho_l}{u_{g,h}^2 \rho_g} \right)^{2/3} \right] \quad [6]$$

All of the quantities appearing on the right-hand side have been defined previously.

Pressure Drop Calculation in the Liquid Phase

The liquid is transported down through the *downcomer*. The capacity of the downcomer should be sufficient to handle the liquid load without becoming the rate limiting factor, i.e. without the liquid backing up the downcomer to a significant extent. Figure 1B shows the pressure differential components making up the total head differential on the liquid side as the liquid backs up the downcomer to a height of h_{dc} . The extent of liquid back-up can be estimated from:

$$h_{dc} = h_t + h_{da} + h_L \quad [7]$$

where h_t is the pressure difference between points a and b in the vapour phase that is necessary to keep the vapour flowing upwards, h_L refers to the effective clear liquid height on the tray deck that must be overcome by the liquid in the downcomer, and h_{da} refers to the pressure loss due to the liquid flow under the downcomer apron. Note that h_t is necessary to keep the upward flow of vapour, but acts as a pressure differential that works against the natural liquid flow in the downcomer. If this pressure differential is large, the liquid will back up more in the downcomer. This points out the coupling between the pressure loss in the vapour phase through the tray deck area and the liquid flow in the downcomer. An optimal design must balance these two factors carefully. h_L and h_t can be estimated from the correlations provided in the previous section. h_{da} can be estimated from:

$$h_{da} = 165.2 U_{da}^2$$

where h_{da} is in millimetres of liquid and U_{da} is the velocity under the downcomer apron in metres per second.

Froth Height and Density Calculation

The froth density (or the two-phase density) has been measured using gamma ray techniques. The average liquid volume fraction on a sieve tray, defined as $\bar{e}_l = h_l/h_b$, is correlated by:

$$\frac{1}{\bar{e}_l} - 1 = c_1 \left[\frac{u_g}{(g h_l)^{0.5}} \left(\frac{\rho_G}{\rho_L} \right)^{0.5} \right]^n \quad [8]$$

Here, h_b is the froth or bed height in metres and u_g is the vapour velocity on bubbling area in metres per second. The constants c_1 and n depend on the type of flow regimes. In the *spray regime*, they take on the values of $c_1 = 265$ and $n = 1.7$, while in the *mixed/emulsion regime*, they are 40 and 0.8. This requires one to estimate the flow regime to be expected under a given set of operating conditions. In Figure 3 of Part I, we identified the limits of operation to lie between the weeping and flooding conditions as the vapour rate is increased. Even within this permissible range of operation, the flow condition has been observed to change from *spray* to *froth* to *emulsion* to *bubble flow* regimes. The transition into the spray regime is given by the capacity factor defined as:

$$CF = u_g \left(\frac{\rho_g}{\rho_l} \right)^{0.5} = 0.85 \frac{g^{0.5} h_l^{1.5} \cdot F}{d_h}$$

Here, CF is the capacity factor defined as $u_g \sqrt{(\rho_G/\rho_L)}$ in metres per second, u_g is the vapour velocity in the bubbling area in metres per second, F is the fractional hole area per unit bubbling area and d_h is the hole diameter in metres. The transition from the spray/froth to emulsion/bubble flow regime is controlled by the ratio of horizontal liquid momentum to vertical vapour momentum and is given by:

$$\frac{u_l}{u_g} \left(\frac{\rho_l}{\rho_G} \right)^{0.5} = \frac{FP}{b \cdot h_l} > 3.0$$

where u_l is the horizontal liquid velocity, u_g is the vapour velocity on bubbling area in metres per second, and FP is the flow parameter defined in eqn [5], b is the weir length per unit bubbling area in metres⁻¹, h_l is the liquid height or hold-up in metres.

Point Efficiency Calculation

There are many empirical correlations for predicting the mass transfer efficiencies on sieve trays. The most recent one is that proposed by Chen and Chuang (1993). It is based on data from industrial sized columns of Fractionation Research Inc. The point effi-

ciency is related to the overall number of transfer units by:

$$E_{OG} = 1 - e^{-N_{OG}} \quad [9]$$

Chen and Chuang present the following correlation for N_{OG} using data free of weeping and entrainment. But the data set spans both the froth and spray regimes:

$$N_{OG} = \frac{11 \frac{1}{\mu^{0.1} \phi^{0.14}} \left[\frac{\rho_L F_s^2}{\sigma^2} \right]^{1/3} (D_G t_G)^{0.5}}{\lambda \frac{11}{14} \left(\frac{D_G \rho_G}{D_L \rho_L} \right)^{0.5} \left(\frac{M_G L}{M_L G} \right) + 1} \quad [10]$$

Here $\lambda = mG/L$ is the separation factor, $F_s = u_s \sqrt{\rho_G}$ is the superficial F-factor in kg^{0.5}/m^{0.5}s, $t_G = h_f/u_s$ is the vapour-phase contact time in seconds, and h_f is the froth height in metres. Note that this correlation combines the *geometrical parameters* such as ϕ , the fractional perforated area, A_b , the bubbling area, the *system properties* such as densities (ρ_L , ρ_G), diffusivities (D_L , D_G) viscosity (μ), the interfacial tension (σ) in newtons per metre, the molecular weights (M_L , M_G), and *operating conditions* such as (L , G), flow rates. This correlation appears to predict the point efficiencies to within 5% of experimental data over a wide range of pressures.

Murphree Tray Efficiency Calculation

The point efficiency model presented above is based on a detailed examination of mass transfer at the vapour/liquid interface. The *ideal equilibrium tray assumption* used in the McCabe-Thiele method asserts that the flow condition on a tray is homogeneous everywhere. If that were true, the point efficiency would be the same everywhere on the tray. But there is strong evidence that the flow is not homogeneous, the degree of inhomogeneity being larger in large diameter columns. Several researchers have tried to measure the velocity profiles across a sieve tray and increasingly computational fluid dynamics is being used as a tool to predict such flow fields. (See for example Solari and Bell (1986) and Mehta *et al.* (1998)). This information on flow profile must be integrated with the point efficiency calculations in order to predict a Murphree tray efficiency. One such method is given below as an illustration. This model considers only the effect of *longitudinal mixing*. A measure of the effective diffusivity, D_E is needed in this model. Models of other flow configuration are discussed in Lockett (1986):

$$\frac{E_{MV}}{E_{OG}} = \frac{1 - e^{-(\eta + Pe)}}{(\eta + Pe) \{ 1 + [(\eta + Pe)/\eta] \}} + \frac{e^{-\eta} - 1}{\eta \{ 1 + [\eta/(\eta + Pe)] \}} \quad [11]$$

where:

$$\eta = \frac{Pe}{2} \left[\left(1 + \frac{4\lambda E_{OG}}{Pe} \right)^{1/2} - 1 \right]$$

and Pe is the Peclet number, defined as $Pe = Z_l^2/D_E t_l$. Here Z_l is the length of liquid travel, or the distance between the two weirs and t_l is the liquid residence time. The effective diffusivity is given by:

$$\sqrt{D_E} = 0.0124 + 0.017u_G + 0.0025L + 0.0150W \quad [12]$$

where D_E is in square feet per second, u_G is superficial gas velocity, expressed as cubic feet per second divided by the active bubbling area in square feet. As the Peclet number becomes large, this model predicts efficiency enhancement much large than unity. In large diameter columns (large Z_l) the *Peclet* number can tend to take a large value which would suggest significant efficiency enhancements. But it should be remembered that the above model considers only the *longitudinal mixing* process. In large diameter columns, the liquid flow structure can be much more complicated as documented by Solari and Bell (1986). Hence, predicted values of E_{MV}/E_{OG} greater than 1.2 by the *longitudinal mixing* model should be viewed with caution, as they may not be realized in the field.

Effect of Entrainment on Murphree Tray Efficiency

The effect of entrainment on the Murphree tray efficiency is estimated from:

$$E_{MV,entrain} = E_{MV} \left[\frac{1}{1 + E_{MV}\psi/(1 - \psi)} \right] \quad [13]$$

where:

$$\psi = \frac{e}{L + e} = \frac{\text{absolute entrainment}}{\text{total liquid flow rate}}$$

where e is the entrained liquid in moles per hour. Zuiderweg presents the following empirical equation to predict the liquid entrainment in the spray regime:

$$\psi = 1.0 \times 10^{-8} \left(\frac{h_b}{H_s} \right)^3 \left(\frac{u_{g,h}}{u_l} \right) \quad \text{for } 0.3 < \frac{h_b}{H_s} < 0.9$$

Here H_s is the tray spacing in metres, h_b is the bed height as defined in eqn [8], $u_{g,h}$ is the vapour velocity in the hole in metres per second and u_l is the horizontal liquid velocity.

Weeping Point Determination

When the vapour velocity is too small, the liquid on a tray deck can flow down through the holes on the

sieve plate, instead of the downcomer, which is the preferred path for the liquid. If weeping is significant, then it results in mixing of liquid streams between two neighbouring trays, thus degrading the performance of the column. The need to avoid weeping places a limit on the minimum vapour velocity. Zuiderweg presents the following correlations to predict the minimum operating limit.

Mixed/free bubbling regime

$$CF_w = F\sqrt{gh_l} \left[1 - 0.15 \frac{FP}{bh_l} \right]$$

Emulsion flow regime

$$CF_w = 0.45F\sqrt{gh_l}$$

where $CF_w = u_g \sqrt{\rho_G/(\rho_L - \rho_G)}$ is the capacity factor at the weep point in metres per second, and F is the fractional hole area per unit bubbling area. Correlations to estimate the type of flow regime are given by Zuiderweg. Note that weeping will seldom occur in the spray regime as vapour velocities are sufficiently large under design conditions. The effect of weeping on the tray efficiency calculation has been studied by Kageyama (1969).

Extensions to Multicomponent Systems

The methods outlined above have been developed largely using experimental data for binary, two-phase systems. The question of whether they can be applied to multicomponent systems can be examined as follows. Tray hydraulics factors such as pressure drops, flow regimes, froth densities, etc., depend only on the fluid mechanics of the two-phase mixture on sieve trays; hence one can expect the correlations to be useful for multicomponent mixtures as long as mixture properties for densities, viscosities, interfacial tensions, etc., are used. On the other hand, the point efficiency (and hence the Murphree tray efficiency) depends on the mass transfer resistance of each component species in each phase. Since the diffusivities and the equilibrium ratios (or the slope of the equilibrium curve, m) could vary for each species, the point efficiency will be different for each species. The correlation given in eqn [10] is based on binary mass transfer data.

In the pseudo binary method of calculation (see Kister, 1992) two components are identified as the *light key* and *heavy key* components and the

Murphree tray efficiency is determined for such a binary pair. One then has the option of either using the efficiency so calculated for all of the remaining components or repeating the procedure for all possible binary pairs. Such detailed estimates of component efficiencies are then used as inputs to advanced process simulators such as ASPEN.

Issues Relating to Scale-up of Efficiency Data

Since the point efficiency data and correlations (like eqn [10] are (or should be) based on local conditions, they should, in principle, remain valid on all scales. They are then integrated with flow conditions to predict the overall tray efficiency. Correlations such as eqn [11], which provide this function of integrating the point efficiency to provide tray efficiency, do not remain valid at all scales. It has been well documented that the liquid flow patterns change quite dramatically depending on the diameter of the column and the location of the weirs near the downcomer. In future one can expect *computational fluid dynamics* to provide detailed flow information using models that remain scale invariant over a wide range of diameters.

Concluding Remarks

A series of correlations taken from the literature are presented. They permit the evaluation of the performance of a sieve tray, once a set of design parameters has been chosen as outlined in Part I. At the design stage of a new sieve tray column, one can embed this design and performance analysis steps into an optimization procedure, in such a way that the design parameters may be altered until a specified objective function is satisfied. The objective function could be

a cost function that includes the capital cost of the equipment (which determines the column diameter, tray spacing, etc.) and operating costs (which determine the reflux and reboil rates and the number of ideal stages).

Vapour-Liquid Equilibrium: Correlation and Prediction

D.-Y. Peng, University of Saskatchewan, Saskatoon, Saskatchewan, Canada

Copyright © 2000 Academic Press

Introduction

Distillation is a process used to separate liquid mixtures into two or more streams, each of which has a composition that is different from that of the

original mixture. The process involves both the vaporization of the original liquid in order to generate the vapours and the subsequent condensation of the vapours to form the desired liquid products. It is evident that vapour-liquid equilibria (VLE) are essential to this separation process. Typical temperature-composition (T - x - y) diagrams, pressure-composition (P - x - y) diagrams, and vapour-liquid composition (x - y) diagrams for completely miscible binary systems are depicted in Figure 1.

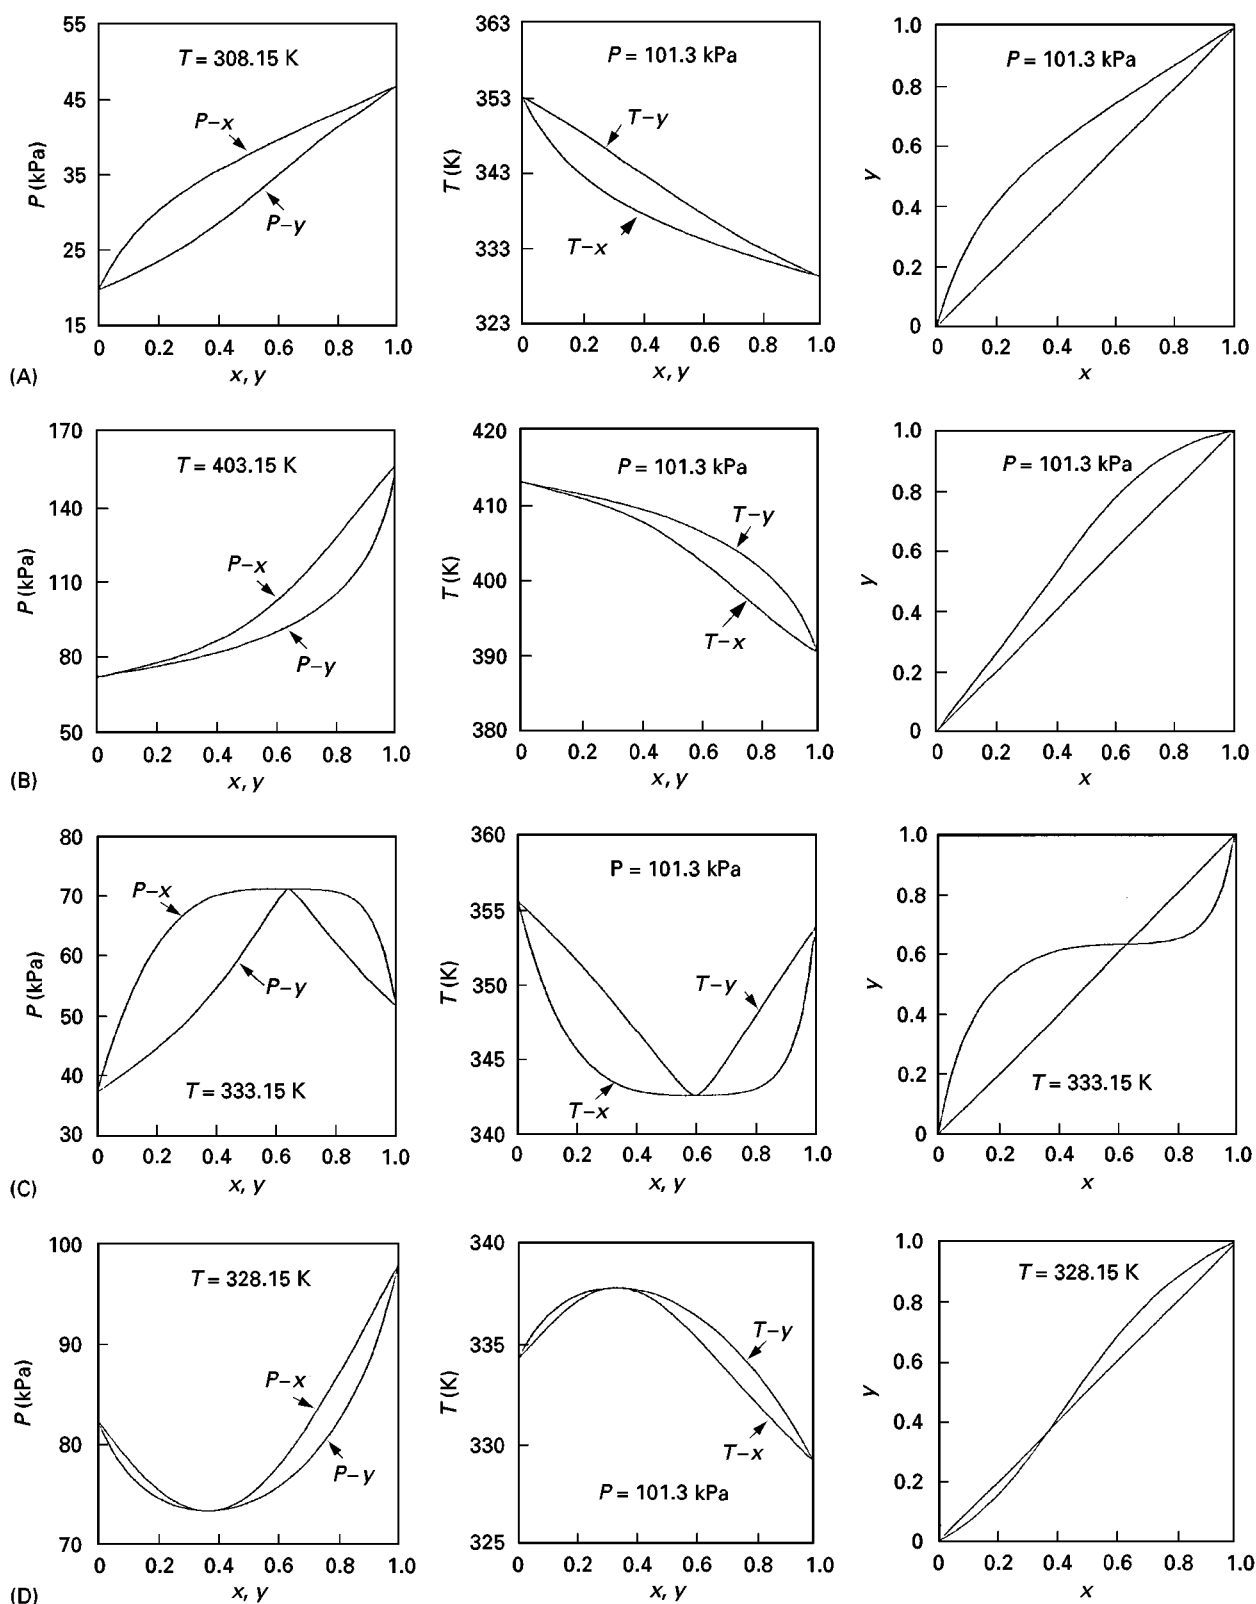

Figure 1 Four types of binary P - x - y , T - x - y and x - y equilibrium phase diagrams. Correlation curves are for: (A) System acetone + benzene. (B) System 1-butanol + acrylic acid. (C) System cyclohexane + 2-propanol. (D) System acetone + chloroform.

Consider an N -component closed system in which a liquid mixture at temperature T and pressure P is in equilibrium with a vapour mixture at the same temperature and pressure. The condition of thermodynamic equilibrium is that the chemical potentials of the components in both phases must satisfy the equality relation:

$$\mu_{iV} = \mu_{iL} \quad (i = 1, 2, \dots, N) \quad (\text{constant } T) \quad [1]$$

The introduction of the quantity called fugacity by G.N. Lewis has facilitated the application of this condition. The fugacity of a system, f , at constant temperature is defined in the following two equations:

$$dG = RT d \ln f \quad [2]$$

and:

$$\lim (f/P) = 1 \quad \text{as } P \text{ approaches zero} \quad [3]$$

where, in eqn [2], G is the molar Gibbs energy.

The fugacity of a component i in a solution is related to the chemical potential of the same component by the equation:

$$d\mu_i = RT d \ln \hat{f}_i \quad [4]$$

A practical expression for vapour-liquid equilibrium consideration thus takes the form:

$$\hat{f}_{iV} = \hat{f}_{iL} \quad [5]$$

where the subscripts V and L indicate fugacity in the vapour phase and liquid phase, respectively. Correlation and prediction of vapour-liquid equilibria must satisfy the equal fugacity condition. The main concern is to relate these fugacities to T , P , and the compositions of the liquid and vapour phases.

Design of distillation operations requires reliable experimental vapour-liquid equilibrium values for conditions corresponding to the desired operation. Available data may frequently be either fragmentary or for conditions different from the desired operating conditions. On many occasions, the needed experimental values are not available at all. In order to make suitable interpolation and extrapolation of the available data, and to make acceptable estimates of unavailable data, it is necessary to take advantage of the limited data available and apply prediction methods developed on the basis of reasonable assumptions. In this article, discussion is limited to correlation and prediction of the vapour-liquid equilibrium values for organic and nonelectrolyte mixtures at conditions such that Raoult's law cannot be

used to represent the behaviour of all components over the complete concentration range. The emphasis is placed on the equilibrium T - P - x - y .

Correlation of Vapour-Liquid Equilibria (VLE)

The quality of the available experimental data is the first concern of any VLE correlation. It is known that a considerable proportion of experimental values are not of good quality owing to the impurity of the chemicals and poor equilibrium stills used, equipment set-ups, and operator errors. In many instances there are quantitative discrepancies among the experimental results for the same system investigated under the same thermodynamic conditions by different authors. Therefore, it is desirable to determine whether the available experimental values are thermodynamically consistent prior to correlation. Consistency tests can be applied whenever the measured properties are more than those that are needed, on the basis of the phase rule, to define the intensive properties of the system under consideration. Although the thermodynamic consistency of experimental data does not guarantee their correctness, inconsistent data are definitely not acceptable.

There are two frequently used methods in correlating vapour-liquid equilibria. One is through the gamma-phi approach, and the other is by means of an equation of state. A comparison of the two methods is presented in Table 1.

Thermodynamic Consistency Test of Data

The Gibbs-Duhem equation is a differential equation that represents the interrelationship among the changes of T , P and composition (in terms of chemical potentials) of an equilibrium system. The equation has the form:

$$-ns dT + nv dP - \sum n_i d\mu_i = 0 \quad [6]$$

When the Gibbs-Duhem equation is applied to the experimental results for systems under isothermal conditions and at low to moderate pressures, eqn [6] is reduced to $\sum n_i d\mu_i = 0$. In terms of liquid activity coefficient, which is defined by:

$$\gamma_i = \hat{f}_{iL}/x_i f_i^{\text{sat}} \quad [7]$$

the simplest expression for testing thermodynamic consistency has the form:

$$\sum x_i d \ln \gamma_i = 0 \quad [8]$$

Table 1 Comparison of vapour-liquid equilibrium calculation methods

Method	Gamma-phi approach	Equation-of-state approach
Advantage	Applicable to a wide variety of mixtures, including polar systems, electrolytes, and polymers. Simple solution models suffice for the correlation of vapour-liquid equilibrium data.	Applicable to a given system over wide ranges of temperature and pressure, including the supercritical region Thermodynamic properties, such as the enthalpy and entropy, can be consistently calculated from the same equation of state.
Disadvantage	Difficult to apply to systems involving supercritical components. Additional correlations must be used to represent the volumetric behaviour and thermal properties.	A single equation cannot represent the properties of all components precisely at the same time. Conventional mixing and combining rules are not applicable to systems containing polar components, polymer molecules, or electrolytes.

In eqn [7], the standard-state fugacity, f_i^{sat} , is the fugacity of component i at the system temperature. The standard state is usually taken to be the pure liquid at the T and P of the system. As data for binary systems are the basis for further correlation, it is desirable to have their consistency tested first. The simplest method is the 'visual test', which is independent of the models of equations used for expressing the excess Gibbs energy. A brief description of the visual test method is presented in **Table 2** with examples depicted in **Figure 2**. More precise testing methods, such as the point-by-point test and the area test, which take into consideration the effect of temperature change on the data for systems at isobaric conditions or the effect of pressure change on the data for systems at isothermal conditions, are available. However, excess enthalpies or volume changes owing to the mixing of components may be required. Whenever the liquid activity coefficients obtained from experimental data can be represented by an integrated Gibbs-Duhem equation (an appropriate modelling equation for γ), the data are considered thermodynamically consistent. For high pressure VLE, testing methods such as those developed by Won and Prausnitz in 1973 and Christiansen and Fredenslund in 1975 may be applied.

Gamma-Phi approach

In the gamma-phi approach, the dimensionless fugacity coefficients ϕ and the activity coefficients γ are used to describe the vapour phase and the liquid phase:

$$\hat{f}_V = \hat{\phi}_i y_i P \quad [9]$$

$$\hat{f}_L = \gamma_i x_i f_i^{\text{sat}} \quad [10]$$

The fugacity coefficients can be calculated from the vapour phase PTv composition data by means of an equation of state, such as the virial equation. When the system pressure is low, either of the volume-explicit virial equation and the pressure-explicit virial equation may be truncated after the second term and used for the calculation. The resulting expressions are respectively:

$$\ln \hat{\phi}_i = (P/RT) \left(2 \sum y_i B_{ij} - B \right) \quad [11]$$

and:

$$\ln \hat{\phi}_i = (2/v) \sum y_i B_{ij} - \ln Z \quad [12]$$

In these two equations, the expression:

$$B = \sum \sum y_i y_j B_{ij} \quad [13]$$

Table 2 Visual test of consistency of activity coefficients for binary systems

1. $\log \gamma_1$ evaluated at $x_1 = 0.25$ should be approximately equal to $\log \gamma_2$ evaluated at $x_1 = 0.75$.
2. Let α be the value of $\log \gamma_1$ evaluated at $x_1 = 0$ and β be the value of $\log \gamma_2$ evaluated at $x_1 = 1$.
 $\log \gamma_1$ evaluated at $x_1 = 0.5$ should be approximately equal to 0.25β .
 $\log \gamma_2$ evaluated at $x_1 = 0.5$ should be approximately equal to 0.25α .
3. If α is greater than or equal to β , then the value of $\log \gamma_1$ evaluated at $x_1 = 0.5$ should be less than or equal to the value of $\log \gamma_2$ evaluated at $x_1 = 0.5$.
4. If α is less than β , then the value of $\log \gamma_1$ evaluated at $x_1 = 0.5$ should be greater than the value of $\log \gamma_2$ evaluated at $x_1 = 0.5$.
5. Both $\log \gamma_i$ versus x_i curves show horizontal tangency as x_i approaches unity and $\log \gamma_i$ approaches zero.
6. If there is a maximum (or minimum) on one of the $\log \gamma_i$ versus x_i curves, there is a corresponding minimum (or maximum) on the other curve at the same x_i .
7. If there is neither a maximum nor a minimum on the curves, both curves should be on the same side of the horizontal line that is representing $\log \gamma_i = 0$.

Figure 2 Visual consistency test of binary vapour-liquid equilibrium of (A) the acetone + benzene system at 318.15 K (Brown I and Smith F (1957) Liquid-vapor equilibrium VIII. The system acetone + benzene and acetone + carbon tetrachloride at 45°C. *Australian Journal of Chemistry* 10: 423–428), (B) the heptane + 3-pentanone system at 368.15 K (Geiseler G and Koehler H (1968) Thermodynamic behavior of the binary systems methyl ethyl ketoxime/n-heptane, diethyl ketone/n-heptane, and methyl ethyl ketoxime/diethyl ketone. *Berichte, Bunsengesellschaft fuer Physikalische Chemie*. 72: 697–706), (C) the toluene + n-octane system at 101.3 kPa. (Bromiley EC and Quiggle, D (1933) Vapor-liquid equilibria of hydrocarbon mixtures. *Industrial and Engineering Chemistry* 25: 1136–1138).

is used for the second virial coefficient of the mixture under consideration. When $i \neq j$, the cross second virial coefficient B_{ij} represents the interaction between molecule i and molecule j . Z is the compressibility factor of the mixture. The ϕ_i values obtained from eqns [11] and [12] are practically identical. A generalized method proposed by Hayden and O'Connell in 1975 may be used for predicting the second virial coefficients for pure components and the cross second virial coefficients. For an ideal gas mixture, $\hat{\phi}_i$ is unity.

Expressions are available for representing the dependence of γ_i on the composition of the solution. The activity coefficients are related to the excess Gibbs energy function by the equation

$$G_i^E = RT \ln \gamma_i \quad [14]$$

where $G_i^E = (\partial n G^E / \partial n_i)_{T,P,n_j}$. Some of these expressions, such as the two-parameter equations of van Laar, those of Margules, and the multiparameter equations of Redlich and Kister, are listed in Table 3. Additional expressions involving higher-order terms, such as those based on the local composition concept proposed by Wilson in 1964, the nonrandom two-liquid (NRTL) model by Renon and Prausnitz in 1968, and the universal quasi-chemical theory (UNIQUAC) equation by Abrams and Prausnitz in 1975, are frequently applied to activity coefficient calculations for binary and multicomponent systems.

According to eqn [8], the relation between $\ln \gamma_1$ and $\ln \gamma_2$ for a binary system at constant temperature and at low to moderate pressure, is given by:

$$x_1(d \ln \gamma_1 / dx_1) + x_2(d \ln \gamma_2 / dx_1) = 0 \quad [15]$$

which indicates that the two activity coefficients are not independent of each other. These activity coefficients may be evaluated by means of the equations listed in Table 4. If the vapour phase can be considered ideal at low pressures, the calculation of γ is much simplified. Pure-component fugacities may be substituted directly by the pure-component vapour pressures:

$$p_i \equiv y_i P = \gamma_i x_i p_i^{\text{sat}} \quad [16]$$

where p_i is the partial pressure of component i , P the system pressure, and p_i^{sat} the vapour pressure of pure component i .

The effect of temperature on $\ln \gamma_i$ is a concern in data correlation; a suitable representation of the temperature effect permits the determination of data for isobaric conditions from data for isothermal conditions, and vice versa. However, a consistency test for isothermal data is much easier than that for isobaric data because the pressure effect is generally much smaller than the temperature effect. The effect of temperature on $\ln \gamma_i$ is related to the partial molar enthalpy. Lu in 1959 considered the variation of excess enthalpies with temperature for binary systems and suggested that the variation of $\ln \gamma_i$ at constant liquid composition be represented by an expression involving three terms for data interpolation and extrapolation:

$$\ln \gamma_i = a + (b/T) + c \ln T \quad (\text{constant composition}) \quad [17]$$

In the absence of excess enthalpy data, isothermal data determined at three conditions suffice for the

Wilson	$G^E/(RT) = -\sum_i x_i \ln (\sum_j x_j \Lambda_{ij})$	$\ln \gamma_i = 1 - \ln (\sum_j x_j \Lambda_{ij}) - \sum_k [x_k \Lambda_{ki} / (\sum_j x_j \Lambda_{kj})]$
NRTL	$\frac{G^E}{RT} = x_1 x_2 \left(\frac{\tau_{21} G_{21}}{x_1 + x_2 G_{21}} + \frac{\tau_{12} G_{12}}{x_2 + x_1 G_{12}} \right)$ where: $\tau_{12} = \frac{\Delta g_{12}}{RT}$, $\tau_{21} = \frac{\Delta g_{21}}{RT}$ $\ln G_{12} = -a_{12} \tau_{12}$, $\ln G_{21} = -a_{12} \tau_{21}$	$\ln \gamma_1 = x_2^2 \left[\tau_{21} \left(\frac{G_{21}}{x_1 + x_2 G_{21}} \right)^2 + \frac{\tau_{12} G_{12}}{(x_2 + x_1 G_{12})^2} \right]$ $\ln \gamma_2 = x_1^2 \left[\tau_{12} \left(\frac{G_{12}}{x_2 + x_1 G_{12}} \right)^2 + \frac{\tau_{21} G_{21}}{(x_1 + x_2 G_{21})^2} \right]$
UNIQUAC	$G^E = G^E(\text{combinatorial}) + G^E(\text{residual})$ $\frac{G^E(\text{combinatorial})}{RT} = x_1 \ln \frac{\Phi_1}{x_1} + x_2 \ln \frac{\Phi_2}{x_2} + 5 \left(q_1 x_1 \ln \frac{\theta_1}{\Phi_1} + q_2 x_2 \ln \frac{\theta_2}{\Phi_2} \right)$ $\frac{G^E(\text{residual})}{RT} = -q_1 x_1 \ln (\theta_1 + \theta_2 \tau_{21}) - q_2 x_2 \ln (\theta_2 + \theta_1 \tau_{12})$ $\Phi_1 = \frac{x_1 r_1}{x_1 r_1 + x_2 r_2}$, $\theta_1 = \frac{x_1 q_1}{x_1 q_1 + x_2 q_2}$ $\ln \tau_{21} = -\frac{\Delta u_{21}}{RT}$, $\ln \tau_{12} = -\frac{\Delta u_{12}}{RT}$	$\ln \gamma_i = \ln \frac{\Phi_i}{x_i} + 5q_i \ln \frac{\theta_i}{\Phi_i} + \Phi_i \left(l_i - \frac{r_i}{r_j} \right) - q_i \ln (\theta_i + \theta_j \tau_{ji}) + \theta_j q_j \left(\frac{\tau_{ji}}{\theta_i + \theta_j \tau_{ji}} - \frac{\tau_{ij}}{\theta_j + \theta_i \tau_{ij}} \right)$ where: $i = 1, j = 2$ or $i = 2, j = 1$ $l_i = \frac{z}{2}(r_i - q_i) - (r_i - 1)$ $l_j = \frac{z}{2}(r_j - q_j) - (r_j - 1)$

determination of isobaric data within a reasonable range of temperatures. Similarly, if isobaric vapour–liquid equilibrium data are available at three conditions, isothermal data can be obtained by the same approach and then tested for consistency. The number of sets of vapour–liquid equilibrium data required can be reduced when excess enthalpies are available, but generally one set of experimental values should be used in the correlation. In the absence of the required data for the determination of parameters in eqn [17], $RT \ln \gamma_i$ at a given composition may be assumed to be constant as an approximation. The correlated results can also be used for the prediction purposes.

Equation-of-State Approach

Fugacities of both phases are represented in this approach by the same equation of state, which provides a relationship between the intensive thermodynamic variables T , P , v and composition. Such an equation may be explicit in P or v . The pressure-explicit equations in the form of:

$$P = P(T, v, x_1, x_2, \dots, x_{n-1}) \quad [18]$$

are more useful for solving phase-equilibrium problems. In terms of the fugacity coefficients, $\hat{\phi}_{iV}(=\hat{f}_{iV}/y_i P)$ and $\hat{\phi}_{iL}(=\hat{f}_{iL}/x_i P)$, formulation of vapour–liquid equilibria is based on the equilibrium

Table 4 Barker's method for the determination of activity coefficients from experimental data

At equilibrium:

$$\begin{aligned} f_i^l &= f_i^v \\ \hat{\phi}_i^v &\equiv \frac{f_i^v}{y_i P} \quad (\text{by definition}) \\ y_i P \hat{\phi}_i^v &= x_i \gamma_i f_i^l \\ \hat{\phi}_i^l &= \frac{f_i^l}{P}, \quad \hat{\phi}_i^{\text{sat}} = \frac{f_i^{\text{sat}}}{p_i^{\text{sat}}} \end{aligned}$$

Therefore:

$$\begin{aligned} y_i P \hat{\phi}_i^v &= x_i \gamma_i \hat{\phi}_i^l P \\ \ln(y_i P \hat{\phi}_i^v) &= \ln(x_i \gamma_i) + \ln \hat{\phi}_i^l + \ln P \\ &= \ln(x_i \gamma_i) + \ln \hat{\phi}_i^{\text{sat}} + \frac{v_i^l}{RT}(P - p_i^{\text{sat}}) + \ln p_i^{\text{sat}} \end{aligned}$$

Hence:

$$\ln \gamma_i = \ln \frac{y_i P}{x_i p_i^{\text{sat}}} + \ln \hat{\phi}_i^v - \ln \hat{\phi}_i^{\text{sat}} - \frac{v_i^l(P - p_i^{\text{sat}})}{RT}$$

For a binary system:

$$B = y_1^2 B_{11} + 2y_1 y_2 B_{12} + y_2^2 B_{22}$$

Let:

$$\delta_{12} = 2B_{12} - B_{11} - B_{22}$$

Then:

$$B = y_1 B_{11} + y_2 B_{22} + y_1 y_2 \delta_{12}$$

At low pressure:

$$\begin{aligned} Z &= \frac{P\tilde{V}}{RT} = 1 + \frac{BP}{RT} \\ \ln \hat{\phi}_1^v &= \left(\frac{B_{11} + y_2^2 \delta_{12}}{RT} \right) P \end{aligned}$$

 For pure component i :

$$\begin{aligned} \ln \phi_i &= \int_0^P (Z_i - 1) \frac{dP}{P}, \quad \left(Z_i = 1 + \frac{B_i P}{RT} \right) \\ \ln \phi_i^{\text{sat}} &= \int_0^{p_i^{\text{sat}}} (Z_i - 1) \frac{dP}{P} = \frac{B_{ii}}{RT} p_i^{\text{sat}} \\ \ln \gamma_1 &= \ln \frac{y_1 P}{x_1 p_1^{\text{sat}}} + \left(\frac{B_{11} + y_2^2 \delta_{12}}{RT} \right) P - \frac{B_{11}}{RT} p_1^{\text{sat}} - \frac{v_1^l(P - p_1^{\text{sat}})}{RT} \\ &= \ln \frac{y_1 P}{x_1 p_1^{\text{sat}}} + \frac{(B_{11} - v_1^l)(P - p_1^{\text{sat}})}{RT} + \frac{y_2^2 \delta_{12} P}{RT} \end{aligned}$$

Similarly:

$$\ln \gamma_2 = \ln \frac{y_2 P}{x_2 p_2^{\text{sat}}} + \frac{(B_{22} - v_2^l)(P - p_2^{\text{sat}})}{RT} + \frac{y_1^2 \delta_{12} P}{RT}$$

 Barker JA (1953) Determination of activity coefficients from total-pressure measurements. *Australian Journal of Chemistry* (1953) 6: 207–210.

equations:

$$y_i \hat{\phi}_{iV} = x_i \hat{\phi}_{iL} \quad (i = 1, 2, \dots, N) \quad [19]$$

$$RT \ln \hat{\phi}_i = \int_V^\infty [(\partial P / \partial n_i)_{T,V,n_j} - RT/V] dV - RT \ln Z \quad [20]$$

 with both the $\hat{\phi}_{iV}$ and $\hat{\phi}_{iL}$ calculated from the equations:

The advantage of this approach is that it is applicable to calculations of VLE at high pressures and it

can also be used to obtain other configurational properties such as enthalpy, entropy and volume changes of mixing, which are useful in the design of distillation columns.

The first equation of state with a theoretical foundation was proposed by van der Waals in 1873, several decades after the ideal gas equation of state had been formulated. This equation not only yields qualitatively correct representation of the phase behaviour of a real fluid, but also provides the basis of the principle of corresponding states. Hundreds of equations of state have been developed since the publication of the van der Waals equation. They may be theoretical, semi-theoretical or empirical. However, most of the modifications are generally limited to a specific purpose.

In order to apply an equation of state to vapour-liquid equilibrium calculations for pure components, a suitable equation should satisfy the three conditions at a given saturation temperature:

$$\nu_{V,\text{calc.}} = \nu_V, \quad \nu_{L,\text{calc.}} = \nu_L, \quad f_{V,\text{calc.}} = f_{L,\text{calc.}} \quad [21]$$

Mixing and combining rules for the equation parameters are required for extending its application to mixtures. However, most of the practical equations available at present have their inherent advantages and disadvantages and may not satisfy both of the volumetric conditions.

The equations of state expressed in terms of polynomials in volume are of practical importance. For VLE calculations, especially when the properties under consideration are limited to T , P and compositions, the simplest and frequently used form is that which is cubic in ν . In spite of their shortcomings, these cubic equations are the most frequently used in practice at present. Currently, the most popular two-parameter cubic equations of state include the Soave-Redlich-Kwong equation (1972):

$$P = RT/(\nu - b) - a/[\nu(\nu + b)] \quad [22]$$

and the Peng-Robinson equation (1976):

$$P = RT/(\nu - b) - a/[\nu(\nu + b) + b(\nu - b)] \quad [23]$$

Both equations can be obtained from a general form of a four-constant cubic equation of the van der Waals type:

$$P = RT/(\nu - b) - a/[(\nu + c_1b)(\nu + c_2b)] \quad [24]$$

Additional multiparameter cubic equations, which are of the form represented by eqn [24] but developed for improving the representations of pure-component

vapour pressures, saturated liquid volumes, the critical compressibility factors, and phase behaviour of polar-nonpolar mixtures, appear continuously in the literature. The maximum number of parameters in a cubic equation is five. A list of some selected cubic equations of state is presented in Table 5. In some of the cubic equations, different repulsion terms (the first term on the right-hand side of the equations listed in the table) have been adopted. The forms of these equations are frequently influenced by the desire to improve the theoretical basis of the equation, and that of fitting the volumetric properties. It should also be mentioned that one of the inherent limitations of a two-parameter equation is that the critical compressibility factor is a constant for all components. The ability of a cubic equation in VLE representation is controlled by the selection of an adequate temperature function for the parameter ' a ' for vapour pressures of pure components, and a set of suitable mixing and combining rules for all the parameters of the equation for mixtures.

Temperature function for ' a ' The importance of using a proper temperature function to represent the parameter ' a ' cannot be overemphasized. In the 1960s, Wilson began the consideration of the temperature effect on the parameter ' a ' of the Redlich-Kwong equation. The expression which has gained wider acceptance was developed by Soave for the same equation in 1972. The parameter ' a ' was expressed by:

$$a = a_c \alpha \quad [25]$$

with α expressed by a function involving the reduced temperature $T_r (= T/T_c)$ in the form:

$$\alpha = [1 + m(1 - T_r^{1/2})]^2 \quad [26]$$

where the subscript c refers to the critical-point condition, and m represents a quadratic function of the acentric factor of Pitzer. This form and its variations have been adopted subsequently in many cubic equations. A selected set of temperature functions for the parameter ' a ' is listed in Table 6.

Mixing and combining rules To extend the application of his equation of state to representing the behaviour of mixtures, van der Waals proposed that the constants ' a ' and ' b ' be expressed by:

$$a = \sum \sum x_i x_j a_{ij} \quad [27]$$

$$b = \sum \sum x_i x_j b_{ij} \quad [28]$$

Twu CH, Bluck D, Cunningham JR and Coon JE (1991) A cubic equation of state with a new alpha function and a new mixing rule. *Fluid Phase Equilibria* 69: 33-50.

The simplest combining rules for ' a_{ij} ' and ' b_{ij} ' are obtained by using the geometric mean for a_{ij} and the arithmetic mean for b_{ij} , i.e:

$$a_{ij} = (a_i a_j)^{1/2} \quad [29]$$

$$b_{ij} = (b_i + b_j)/2 \quad [30]$$

A binary interaction parameter k_{ij} is frequently introduced in eqn [29] to correct the discrepancy generated by the geometric mean:

$$a_{ij} = (a_i a_j)^{1/2} (1 - k_{ij}) \quad [31]$$

Occasionally, a binary interaction parameter l_{ij} is introduced in eqn [30] to yield improved b_{ij} values:

$$b_{ij} = (b_i + b_j)(1 - l_{ij})/2 \quad [32]$$

More recently, new mixing rules, such as the one proposed by Wong and Sandler in 1992, with im-

proved theoretical considerations have appeared in the literature. A list of some mixing and combining rules is presented in Table 7.

In general, vapour-liquid equilibrium of a great variety of mixtures, including polar-nonpolar mixtures, can be well represented. For a given mixture, the equation-of-state mixing rules with one set of parameters can frequently represent the data over wide ranges of temperature and pressure.

Examples of binary data representation by means of the two approaches are depicted in Figure 3.

Prediction of Vapour-Liquid Equilibria

Although vapour-liquid equilibria have been investigated for more than 10 000 systems, values resulting from various combinations are still unknown. It would be impractical to determine experimentally all the systems needed individually.

In principle, experimental values of some thermodynamic properties can be used to estimate other properties. For examples, binary vapour-liquid equilibrium can be estimated from the liquid activity coefficients calculated from mutual solubility data for the same mixture, and the infinite-dilution activity coefficients measured from gas-liquid chromatography can be used to predict the vapour-liquid equilibria over the complete concentration range. Some prediction methods are briefly described below with emphasis placed on binary mixtures. Extending the

application to multicomponent mixtures is feasible once good correlation of the vapour–liquid equilibria of its constituent binary systems becomes available.

Prediction from Pure Component Properties

Application of the regular solution theory For mixtures containing nonpolar components that are not much different in size and shape, the regular solution theory of Hildebrand leads to a semi-quantitative prediction of γ_k values of all components in a mixture. In terms of the solubility parameter, the activity coefficients of the components in a regular solution can be calculated from the equation:

$$RT \ln \gamma_k = v_k (\delta_k - \delta)^2 \quad [33]$$

where the volume average solubility parameter is given by:

$$\delta = \sum \Phi_i \delta_i \quad [34]$$

and the volume fraction Φ_i is defined by:

$$\Phi_i = x_i v_i / \sum x_j v_j \quad [35]$$

The solubility parameter for substance k , δ_k , is defined by:

$$\delta_k = (\Delta U_k^V / v_k^V)^{1/2} = [(\Delta H_k^V - RT) / v_k^V]^{1/2} \quad [36]$$

where ΔU_k^V and ΔH_k^V are, respectively, the molar energy and enthalpy of vaporization of pure liquid k at temperature T . The assumption involved here is that T is well below the critical temperature in order to make the approximation valid. The calculated liquid activity coefficients can then be used to obtain the desired vapour–liquid equilibrium values. For a binary mixture:

$$RT \ln \gamma_1 = v_1 \Phi_2^2 (\delta_1 - \delta_2)^2 \quad [37]$$

$$RT \ln \gamma_2 = v_2 \Phi_1^2 (\delta_1 - \delta_2)^2 \quad [38]$$

Should a binary interaction parameter be required to improve the data representation, an extension of the approach to the prediction of multicomponent vapour–liquid equilibrium may not be practical; attempts made to correlate the binary parameters have not been successful.

Liquid activity coefficients at infinite dilution γ^∞ Values of γ^∞ are particularly useful for obtaining the parameters of any of the two-constant equations for the excess Gibbs energy; the γ^∞ values for a binary system are the parameter values. For example, $\gamma_1^\infty = A$ and $\gamma_2^\infty = B$ for the van Laar and Margules equations presented in Table 3. If a three-parameter equation is used, the third parameter must be determined by an independent approach.

The modified separation of cohesive energy density (MOSCED) method proposed by Thomas and Eckert

in 1984 may be used to predict γ^∞ values from pure component parameters. This method is based on a modified regular solution theory and the assumption that the forces contributing to the cohesive energy are additive. It has been reported that the average error of 3357 γ^∞ values predicted by this method was 9.1%.

In general, calculated equilibrium vapour compositions are relatively insensitive to moderate errors in the γ^∞ used in the calculation.

Prediction of Binary γ Values Using Azeotropic or Mutual Solubility Data

Prediction from azeotropic data Many binary systems exhibit azeotropic behaviour. At an azeotropic condition, the compositions of the liquid and vapour phases are identical. At low pressures, the liquid activity coefficients can be simply calculated by:

$$\gamma_1 = P/p_1^{\text{sat}} \quad \text{and} \quad \gamma_2 = P/p_2^{\text{sat}} \quad [39]$$

The parameters of any two-parameter expression of the excess Gibbs energy can then be obtained and used for extrapolating vapour-liquid equilibrium over the complete concentration range.

Prediction of γ values from mutual solubility data

The thermodynamic consideration applicable to a binary system at vapour-liquid equilibrium is also applicable to a partially miscible binary liquid mixture at equilibrium. Hence, the activity coefficients of the two liquids at the temperature at which the solubilities were experimentally determined can be expressed by:

$$\gamma'_1 x'_1 = \gamma''_1 x''_1 \quad \text{and} \quad \gamma'_2 x'_2 = \gamma''_2 x''_2 \quad [40]$$

where the two superscripts refer to the two liquid phases. Applying these relationships to any two-parameter expression of the excess Gibbs energy leads to the determination of the parameter values, which permit vapour-liquid equilibrium estimation of the mixture.

Prediction of γ from Group Contribution Methods

In group contribution methods, the calculation of thermodynamic properties of pure fluids is based on the assumption that each molecule is an aggregate of functional groups. Langmuir in 1925 extended the concept to mixtures. Redlich, Derr, Pierotti and Papadopoulos developed a group interaction model for heats of solution in 1959. Adopting the concepts presented by these authors, Wilson and Deal suggested in 1962 a solution of the groups approach by

which liquid activity coefficients can be estimated on the basis of group contributions. In this approach, the logarithm of the activity coefficient of a component is assumed to be the sum of two contributions: the configurational contribution, which accounts for the differences in molecular size, and the group interaction contribution, which accounts for the intermolecular forces originating from the different functional groups.

The group contribution approach to calculating γ is attractive because through this approach it is possible to estimate vapour-liquid equilibria of nonideal mixtures without experimentation. Although a large number of mixtures can result from pure compounds, the functional groups, such as CH_2 , OH, CO, COO and COOH, that constitute these compounds are limited. If the activity coefficients of the mixture components could be obtained from a knowledge of the interactions of these groups, and with the assumption that the contribution to γ by one group within a molecule is independent of that made by any other group in that molecule, a relatively small number of parameters would suffice for the prediction of the activity coefficients for mixtures containing the same groups. This assumption implies that the contribution of the group interaction is independent of the nature of the molecule.

Two of these approaches are mentioned here.

Analytical solutions of groups (ASOG) method

Following the concept of the solutions of groups of Wilson and Deal, the analytical solutions of groups (ASOG) method was first presented by Derr and Deal in 1969. Basically, the practical application of the solutions of groups concept involves the reduction of liquid activity coefficients obtained from experimental data for vapour-liquid equilibria into a number of binary group interaction parameters. The working equations of the ASOG method are presented in Table 8.

Kojima and Tochigi in 1979 calculated the group interaction parameters for 31 groups and used the method to predict the vapour-liquid equilibria for 936 binary systems, 103 ternary systems, five quaternary systems, and two quinary systems at low pressures. They reported that the average absolute deviation of the predicted vapour compositions was 1.2%.

Universal functional group activity coefficient (UNIFAC) method

The universal functional group activity coefficient (UNIFAC) method proposed by Fredenslund, Gmehling and Rasmussen and the ASOG method are based on the same principle of group contributions. The main difference between these two methods is in the equations used for

Table 8 The analytical solution of groups (ASOG) method

1. $\ln \gamma_i = \ln \gamma_i^S + \ln \gamma_i^G$
2. $\ln \gamma_i^S = 1 - r_i - \ln r_i$
 where: $r_i = \frac{v_i}{\sum_j x_j v_j}$
 x_j = mole fraction of molecule j
 v_j = number of atoms other than hydrogen in molecule j
3. $\ln \gamma_i^G = \sum_k v_{ki} (\ln \Gamma_k - \ln \Gamma_k^{(i)})$
 where: v_{ki} = number of atoms other than hydrogen in group k in molecule i
 $\ln \Gamma_k = 1 - C_k - \ln D_k$
 $\ln \Gamma_k^{(i)} = 1 - C_k^{(i)} - \ln D_k^{(i)}$
 $C_k = \sum_j \frac{X_j A_{jk}}{D_j}, \quad C_k^{(i)} = \sum_j \frac{X_j^{(i)} A_{jk}}{D_j}$
 $D_k = \sum_j X_j A_{kj}, \quad D_k^{(i)} = \sum_j X_j^{(i)} A_{kj}$
 $X_L = \frac{1}{S} \sum_i x_i v_{Li}, \quad X_L^{(i)} = \frac{v_{Li}}{\sum_k v_{ki}}$
 $A_{kL} = \exp\left(m_{kL} + \frac{n_{kL}}{T}\right)$
 $S = \sum_i x_i \sum_k v_{ki}$

representing the excess Gibbs energy. The Wilson equation is used in the ASOG method, whereas the two-parameter universal quasi-chemical (UNIQUAC) equation of Abrams and Prausnitz is used in the UNIFAC method. The working equations of the UNIFAC method are presented in Table 9. There are 50 main groups together with their subgroups for the determination of the parameters involved in the calculation. For γ calculations for multicomponent systems, the adjustable binary parameters are evaluated from binary vapour–liquid equilibrium data.

Prediction using Equations of State

The equations of state successfully used for correlation of binary vapour–liquid equilibria can be used for the purposes of predicting multicomponent vapour–liquid equilibria, provided that the binary interaction parameters of all the constituent binary systems are available. All the parameters should be obtained by regression of the binary data using the same mixing and combining rules. Interpolated and estimated values of these parameters are available for some systems, but their values are subject to frequent revision.

Additional Comments on Applications

There is no simple equation of state that can represent satisfactorily the three conditions of eqn [21] over

a wide range of temperature. Experience indicates that equations that could meet the equal fugacity condition as well as v_v or v_L would be suitable for the intended vapour–liquid equilibrium calculations. Should a situation arise such that the saturated liquid molar volume is required in the estimation, cubic equations containing more parameters may be selected for the representation. Adachi and Lu in 1990 suggested that it is possible to assign different two-parameter or three-parameter cubic equations to different components of the binary mixture under consideration, and then use a four-parameter cubic equation to combine the equations in the vapour–liquid equilibrium calculations for mixtures.

Special case should be applied when equations of state are used to represent the experimental data measured at or near theoretical points of the fluids.

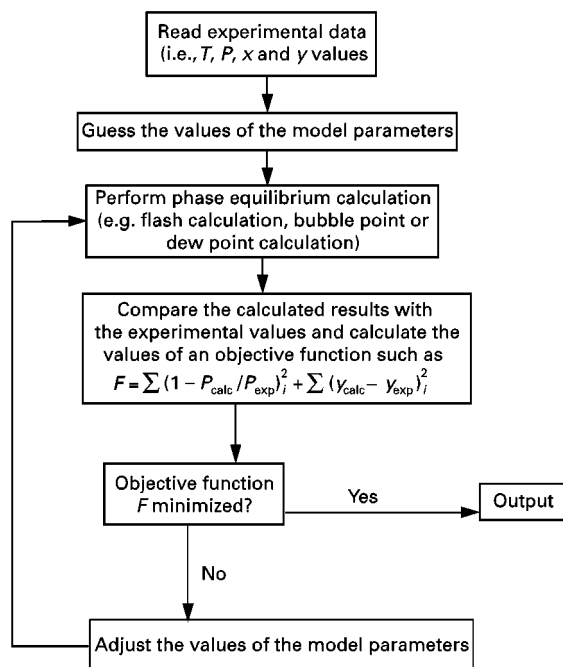

The selection of mixing and combining rules plays a crucial role in the application of equations of state to the correlation and prediction of vapour–liquid equilibria. The importance of selecting an appropriate expression for the excess Gibbs energy cannot be overemphasized.

The prediction of binary vapour–liquid equilibria from pure-component properties by means of the MOSCED method is attractive. However, poor results are obtained for systems where steric considerations are significant. The general applicability of this model is limited due to the difficulties involved in

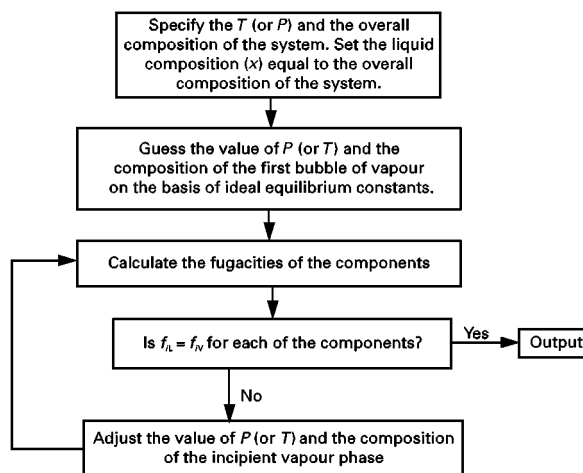

Table 9 The UNIFAC method

1. $\ln \gamma_i = \ln \gamma_i^G + \ln \gamma_i^R$
2. $\ln \gamma_i^G = 1 - J_i + \ln J_i - 5q_i \left(1 - \frac{J_i}{L_i} + \ln \frac{J_i}{L_i}\right)$
 where: $J_i = \frac{r_i}{\sum_j x_j r_j}, \quad L_i = \frac{q_i}{\sum_j x_j q_j}$
 $r_i = \sum_k v_k^{(i)} R_k, \quad q_i = \sum_k v_k^{(i)} Q_k$
 R_k = volume parameter for group k
 Q_k = surface area parameter for group k
 $v_k^{(i)}$ = number of subgroups of type k in molecule of species i
3. $\ln \gamma_i^R = q_i \left[1 - \sum_k \left(\frac{\theta_k \beta_{ik}}{S_k} - \rho_{ki} \ln \frac{\beta_{ik}}{S_k}\right)\right]$
 where: $\rho_{ki} = \frac{v_k^{(i)} Q_k}{q_i}$
 $\beta_{ik} = \sum_m \rho_{mi} \tau_{mk}$
 $\theta_k = \frac{\sum_i x_i q_i \rho_{ki}}{\sum_i x_i q_i}$
 $S_k = \sum_m \theta_m \tau_{mk}$
 $\tau_{mk} = \exp\left(-\frac{\alpha_{mk}}{T}\right)$
 α_{mk} = group interaction parameter

(C) Dew point calculation

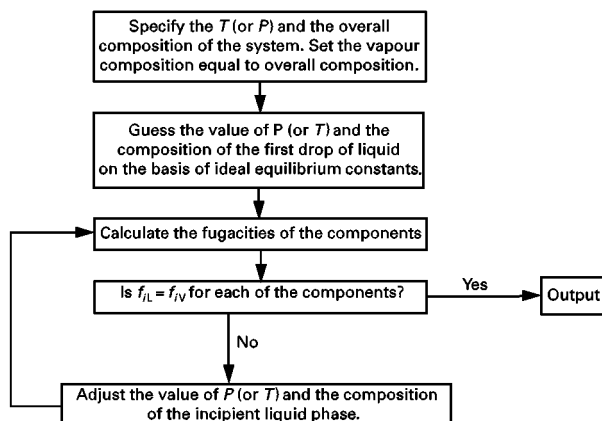

Figure 4 Algorithms for correlating and predicting vapour–liquid equilibrium values.

the determination of pure component parameters. Furthermore, the approach cannot be used for aqueous mixtures, nor for systems with very large γ^∞ values.

In general, the accuracy of prediction depends on the availability of some reliable binary data for either the system of interest or another one that is closely related to it.

All the group-contribution methods are approximate. The fundamental assumption involved in the group solution approach is additivity, and the estimated γ values are necessarily approximate.

Finally, computer software packages for vapour–liquid equilibrium calculations are available commercially from a number of process engineering software

development companies. Typical algorithms for data correlation and prediction are depicted in Figure 4.

Vapour-Liquid Equilibrium: Theory

A. S. Teja and L. J. Holm, Georgia Institute of Technology, Atlanta, GA, USA

Copyright © 2000 Academic Press

Introduction

The concept of an equilibrium stage in distillation is based on the assumption that the vapour leaving the

stage is in equilibrium with the liquid leaving the same stage. The use of this concept in the design of distillation columns requires a description of how the components of a multicomponent mixture distribute between the two phases in equilibrium. This description is provided by phase equilibrium thermodynamics.

The equilibrium relationship for any component i in an equilibrium stage is defined in terms of the

distribution coefficient or K value:

$$K_i = \frac{y_i}{x_i} \quad [1]$$

where y_i is the mole fraction of component i in the vapour phase and x_i is the mole fraction of i in the liquid phase. The more volatile components of a mixture will have higher K values, and vice versa. In distillation, the efficiency of separation of two components is often compared via a quantity called the relative volatility α_{ij} :

$$\alpha_{ij} = \frac{K_i}{K_j} = \frac{y_i/x_i}{y_j/x_j} \quad [2]$$

A relative volatility close to unity means that the separation of the two components is likely to be difficult, whereas a relative volatility much greater or much less than unity means that few equilibrium stages are likely to be needed for separation. For binary system, eqn [2] can be rearranged to give:

$$y_i = \frac{\alpha_{ij}x_i}{1 + (\alpha_{ij} - 1)x_i} \quad [3]$$

Eqn [3] is plotted in **Figure 1** for various (constant) values of the relative volatility. Note that an increase in the relative volatility leads to an increase in the concentration of the more volatile component in the vapour phase. When the relative volatility has a value of 1, $y_i = x_i$ and separation is no longer feasible. A relative volatility of 1 also signifies the existence of an azeotrope or a critical point. A framework for the correlation and prediction of K values (and hence

Figure 1 The y - x behaviour of a binary mixture at constant temperature for various values of the relative volatility α_{ij} .

relative volatilities) is provided by thermodynamics and is discussed below. A more detailed discussion may be found in textbooks of thermodynamics (see Further Reading).

Thermodynamic Framework

Vapour–liquid equilibria (VLE) can be modelled using the thermodynamic relationship for the equality of fugacities of a component i in the vapour and liquid phases. Thus:

$$\hat{f}_i^L = \hat{f}_i^V \quad (i = 1 \text{ to } m) \quad [4]$$

where m is the total number of components in the system, and L and V represent the liquid phase and the vapour phase, respectively. In order to use this relationship, the fugacities must first be related to the compositions in the two phases in equilibrium. This is done using the following thermodynamic relationship in terms of the variables T , P and n_i :

$$RT \ln \left(\frac{\hat{f}_i}{z_i P} \right) = \int_0^P \left[\left(\frac{\partial V}{\partial n_i} \right)_{T,P,n_j} - \frac{RT}{P} \right] dP \quad [5]$$

or the equivalent relationship in terms of T , V and n_i :

$$RT \ln \left(\frac{\hat{f}_i}{z_i P} \right) = \int_V^\infty \left[\left(\frac{\partial P}{\partial n_i} \right)_{T,V,n_j} - \frac{RT}{V} \right] dP - RT \ln \left(\frac{PV}{RT} \right) \quad [6]$$

In the above equations, z_i is either x_i or y_i depending on the phase being considered, and n_i is the number of moles of component i in that phase. The quantity $(\hat{f}_i/z_i P)$ is called the fugacity coefficient $\hat{\phi}_i$ of component i in the mixture.

Ideal Systems

In the case of an ideal gas mixture, substitution of the ideal gas equation $PV = nRT$ into eqn [5] leads to:

$$\hat{f}_i^V = y_i P \quad [7]$$

Similarly, substitution of the volume additivity relation for ideal liquid mixtures $V = \sum n_i v_i^L$ (where v_i^L is the molar volume of component i at the temperature and pressure of the solution) leads to:

$$\hat{f}_i^L = x_i f_i^L \quad [8]$$

where f_i^L is the fugacity of pure liquid i at the pressure and temperature of the solution. At constant temperature, the effect of pressure on the pure liquid

fugacity can be obtained from:

$$d \ln f_i^L = \frac{v_i^L}{RT} dP \quad [9]$$

Integration of eqn [9] from the saturation pressure to the system pressure leads to:

$$f_i^L = f_i^{\text{sat}} \exp \int_{P_i^{\text{sat}}}^P \frac{v_i^L}{RT} dP \quad [10]$$

where $f_i^{\text{sat}} (= \phi_i^{\text{sat}} P_i^{\text{sat}})$ is the fugacity of pure i at saturation, ϕ_i^{sat} is the fugacity coefficient of pure i at saturation, and P_i^{sat} is the vapour pressure of pure i . The liquid molar volume v_i^L can often be assumed to be constant with respect to pressure (since liquids are incompressible), thus simplifying the exponential terms of eqn [10], called the Poynting factor, to:

$$\exp \left(- \int_{P_i^{\text{sat}}}^P \frac{v_i^L}{RT} dP \right) \approx \exp \left(\frac{v_i^L (P_i^{\text{sat}} - P)}{RT} \right) \quad [11]$$

At low pressures ($P < 1$ MPa), the Poynting terms and ϕ_i^{sat} both approach unity and eqn [10] reduces to:

$$f_i^L = P_i^{\text{sat}} \quad [12]$$

Thus, for the simplest case of an ideal gas mixture in equilibrium with an ideal liquid solution at low pressures, eqns [4]–[12] lead to Raoult's law:

$$x_i P_i^{\text{sat}} = y_i P \quad [13]$$

and, therefore:

$$K_i = \frac{y_i}{x_i} = \frac{P_i^{\text{sat}}}{P} \quad [14]$$

and:

$$\alpha_{ij} = \frac{P_i^{\text{sat}}}{P_j^{\text{sat}}} \quad [15]$$

The relative volatility of a system that obeys Raoult's law is thus a ratio of two vapour pressures and is a function only of the temperature. The y_i versus x_i behaviour at constant temperature is therefore as shown in Figure 1, and the P - x - y behaviour of such a system is shown in Figure 2. A feature of this system is that the P - x behaviour (or the bubble curve) is linear and given by:

$$P = P_i^{\text{sat}} + x_1 (P_1^{\text{sat}} - P_2^{\text{sat}}) \quad [16]$$

Only a small number of systems containing chemically similar components obey Raoult's law, and then

Figure 2 The P - x - y behaviour at constant temperature of a binary mixture that obeys Raoult's law. The dashed line shows the P - x behaviour or the bubble curve. The solid line represents the P - y behaviour or the dew point curve.

only at low pressures (< 1 MPa). As a consequence, K values can be predicted from pure component data only for such mixtures. The majority of real systems are nonideal and their thermodynamic description is discussed below.

Nonideal Systems

Figure 3A, B shows the P - x - y behaviour of systems that exhibit small negative and positive deviations from Raoult's law, whereas Figure 3C and D show systems that exhibit large negative and positive deviations from Raoult's law, respectively. Large deviations from Raoult's law often lead to the formation of minimum pressure (maximum boiling) or maximum pressure (minimum boiling) azeotropes, as shown in Figure 3C and D. The relative volatility has a value of unity at the azeotropic composition. Nonideal behaviour depicted in these figures can be described using two approaches – the activity coefficient approach and the equation of state approach.

Activity coefficient approach In this approach, vapour-phase fugacities are written in terms of the vapour-phase composition as follows:

$$\hat{f}_i^V = \hat{\phi}_i^V y_i P \quad [17]$$

where $\hat{\phi}_i^V$ is the vapour-phase fugacity coefficient of component i , y_i is the mole fraction of i in the vapour phase and P is the total system pressure. In addition, liquid-phase fugacities are written in terms of the liquid-phase composition as follows:

$$\hat{f}_i^L = \gamma_i x_i f_i^0 \quad [18]$$

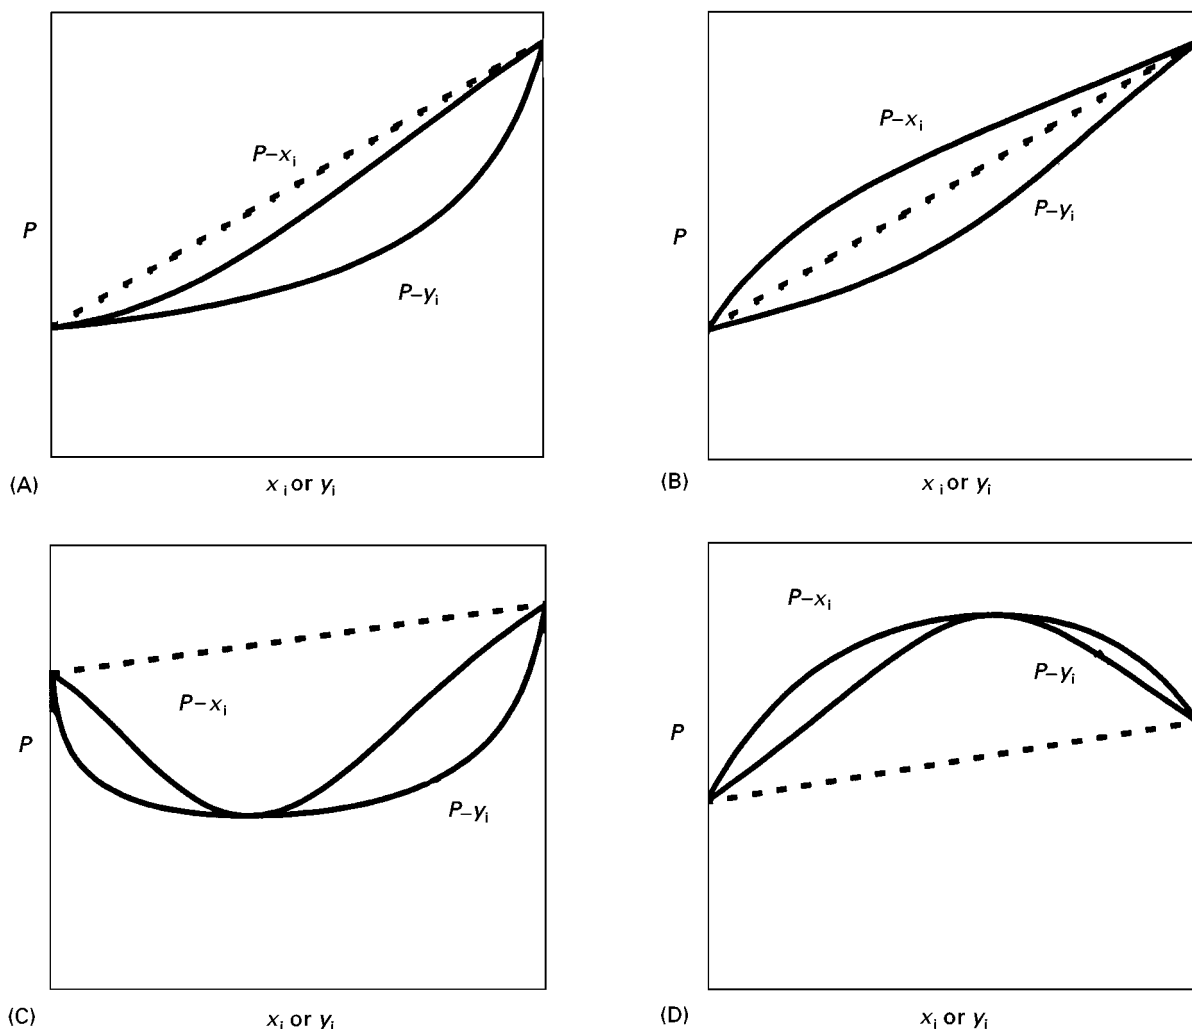

Figure 3 (A) The P - x - y behaviour of a system that exhibits small negative deviations from Raoult's law. The P - x behaviour of a system that follows Raoult's law is shown by the broken line. (B) The P - x - y behaviour of a system that exhibits small positive deviations from Raoult's law. Raoult's law behaviour is shown by the broken line. (C) The P - x - y behaviour of a system that exhibits significant negative deviations from Raoult's law leading to the formation of a minimum pressure (maximum boiling) azeotrope. (D) The P - x - y behaviour of a system that exhibits significant positive deviations from Raoult's law leading to the formation of a maximum pressure (minimum boiling) azeotrope.

where γ_i is the activity coefficient of component i in the liquid phase, x_i is the mole fraction of i in the liquid phase and f_i^0 is the fugacity of pure liquid i at the pressure and temperature of the system. Combining eqns [17] and [18], we obtain:

$$\gamma_i x_i f_i^0 = \hat{\phi}_i^V y_i P \quad [19]$$

At low pressures (< 1 MPa), eqn [19] can be simplified further to yield:

$$\gamma_i x_i P_i^{\text{sat}} = \hat{\phi}_i^V y_i P \quad [20]$$

as discussed in the previous section. Often $\hat{\phi}_i^V \sim 1.0$ for vapour phases at moderate pressures.

Hence:

$$\gamma_i x_i P_i^{\text{sat}} = y_i P \quad [21]$$

and:

$$K_i = \gamma_i P_i^{\text{sat}} / P \quad [22]$$

Vapour pressures at subcritical temperatures may be obtained from experimental data using equations such as the Antoine equation. Activity coefficients may be obtained from excess Gibbs energy g^E models, as described below.

Equation of state approach The equation of state approach uses eqn [17] for the vapour phase and an

analogous expression for the liquid phase. Thus, for the liquid phase:

$$\hat{f}_i^L = \hat{\phi}_i^L x_i P \quad [23]$$

Substituting these relationships into eqn [4] results in:

$$\hat{\phi}_i^V y_i = \hat{\phi}_i^L x_i \quad [24]$$

and:

$$K_i = \hat{\phi}_i^L / \hat{\phi}_i^V \quad [25]$$

The calculation of K values is therefore reduced to the calculation of fugacity coefficients in the equation of state approach and, at moderate pressures, to the calculation of activity coefficients in the activity coefficient approach.

Calculation of Fugacity Coefficients

Calculation of the fugacity coefficient using eqn [5] or eqn [6] requires knowledge of the P - V - T - x behaviour of the system. This information is obtained from an equation of state. Two representative types of equation of state will be discussed below – a volume-explicit virial equation and a pressure-explicit cubic equation. A more detailed discussion of types of equation of state is available elsewhere (see Further Reading).

Volume-explicit Virial Equation

Virial equations of state are infinite-series expansions of the compressibility Z as a function either of the density or pressure. The pressure series may be written as:

$$\begin{aligned} Z = \frac{PV}{RT} &= 1 + B'P + C'P^2 + \dots \\ &= 1 + \frac{BP}{RT} + \frac{(C - B^2)}{(RT^2)}P^2 + \dots \end{aligned} \quad [26]$$

where B is the second virial coefficient, C the third virial coefficient, and so on. Typically, the two-terms truncated form of the virial equation is used for gases at low pressures:

$$Z = 1 + B'P = 1 + \frac{BP}{RT} \quad [27]$$

which can be rearranged in the volume-explicit form:

$$V = \frac{RT}{P} + B \quad [28]$$

The truncated virial eqn [28] is only applicable to gases at densities that are less than about half the critical density. One of the advantages of the virial equation, however, is that virial coefficients can be calculated from intermolecular potential functions. Also, statistical mechanics provides rigorous expressions for the composition dependence of the virial coefficients. Thus, the mixture second virial coefficient is given by:

$$B = \sum_i \sum_j y_i y_j B_{ij} \quad [29]$$

where B_{ii} is the second virial coefficient of component i and B_{ij} is a cross second virial coefficient. Substitution of eqns [28] and [29] into eqn [5] leads to:

$$\ln \hat{\phi}_i^V = \frac{P}{RT} [B_{ii} + \frac{1}{2} \sum_k \sum_l y_k y_l (2\delta_{ki} - \delta_{kl})] \quad [30]$$

where $\delta_{kl} = 2B_{kl} - B_{kk} - B_{ll}$. The fugacity coefficient of any component in the vapour phase can thus be calculated if the second virial coefficients of the pure components and the cross second virial coefficients are available. Since the truncated virial equation is only applicable to gases at low to moderate pressures, fugacity coefficients calculated using eqn [30] are generally only employed when eqn [20] is used to calculate VLE.

Pressure-explicit Cubic Equation of State

Cubic equations of state express the pressure as a cubic function of the molar volume, and their origin stems from the van der Waals equation, which was the first cubic equation of state to represent qualitatively both vapour and liquid phases. Several hundred modification of the van der Waals equation have been reported in the literature. An example of a recent modification that is better able to represent P - V - T - x data for both vapour and liquid mixtures is the equation of state proposed by Patel and Teja in 1982. This equation may be written as:

$$P = \frac{RT}{v - b} - \frac{a\alpha}{v^2 + bv + cv - bc} \quad [31]$$

where:

$$a = \alpha \Omega_a \frac{R^2 T_c^2}{P_c} \quad [32]$$

$$b = \Omega_b \frac{RT_c}{P_c} \quad [33]$$

$$c = \Omega_c \frac{RT_c}{P_c} \quad [34]$$

$$\alpha = [1 + m(1 - \sqrt{T/T_c})]^2 \quad [35]$$

$$\Omega_a = 3\zeta_c^2 + 3(1 - 2\zeta_c)\Omega_b + \Omega_b^2 + 1 - 3\zeta_c \quad [36]$$

$$\Omega_c = 1 - 3\zeta_c \quad [37]$$

$$\zeta_c = P_c v_c / RT_c \quad [38]$$

and Ω_b is the smallest positive root of:

$$\Omega_b^3 + (2 - 3\zeta_c)\Omega_b^2 + 3\zeta_c^2\Omega_b - \zeta_c^3 = 0 \quad [39]$$

In the above equations, the subscript c denotes a value at the critical point. Note that by setting the parameter $c = 0$ in eqn [31], the Patel-Teja equation reduces to the Redlich-Kwong-Soave equation of state; and by setting $c = b$, it reduces to the Peng-Robinson equation of state. Both the Redlich-Kwong-Soave and the Peng-Robinson equations are widely used in process design calculations. For non-polar fluids, ζ_c and m are calculated from the following relationships in terms of the acentric factor ω :

$$\zeta_c = 0.329032 - 0.076799\omega + 0.0211947\omega^2 \quad [40]$$

$$m = 0.452413 + 1.30982\omega - 0.295937\omega^2 \quad [41]$$

A knowledge of P_c , T_c and ω is therefore sufficient to calculate the parameters of the equation of state. Alternatively, ζ_c and m may be calculated from experimental values of the vapour pressure and liquid density of the substance. Several other forms of eqn [35] suitable for complex molecules have been proposed.

The parameters a , b and c for a mixture can be calculated using the following mixing rules:

$$a\alpha = \sum_i \sum_j z_i z_j (a\alpha)_{ij} \quad [42]$$

$$b = \sum_i z_i b_i \quad [43]$$

$$c = \sum_i z_i c_i \quad [44]$$

where z_i can be x_i or y_i and $(a\alpha)_{ij} = (1 - k_{ij})\sqrt{(a\alpha)_i(a\alpha)_j}$, k_{ij} is a binary interaction parameter that is usually obtained by fitting experimental VLE data.

The fugacity coefficient can be obtained by substituting eqns [31]–[44] into eqn [6] leading to:

$$\ln \hat{\phi}_i = \ln \left(\frac{\hat{f}_i}{z_i P} \right) = \frac{b_i}{v - b} - \ln \left[\frac{P}{RT} (v - b) \right] - \frac{2 \sum_j x_j \alpha_{ij} a_{ij}}{RT[4bc + (b + c)^2]^{1/2}}$$

$$\begin{aligned} & \times \ln \left(\frac{(2v + b + c) + [4bc + (b + c)^2]^{1/2}}{(2v + b + c) - [4bc + (b + c)^2]^{1/2}} \right) \\ & + \frac{2a\alpha(b_i + c_i)}{RT((2v + b + c)^2 - [4bc + (b + c)^2])} \\ & + \frac{a\alpha}{RT[4bc + (b + c)^2]^{3/2}} \\ & \times [c_i(3b + c) + b_i(3c + b)] \\ & \times \left[\ln \left(\frac{(2v + b + c) + [4bc + (b + c)^2]^{1/2}}{(2v + b + c) - [4bc + (b + c)^2]^{1/2}} \right) \right. \\ & \left. - \frac{2(2v + b + c)[4bc + (b + c)^2]^{1/2}}{(2v + b + c)^2 - [4bc + (b + c)^2]} \right] \quad [45] \end{aligned}$$

Eqn [45] can be used to calculate both the vapour- and liquid-phase fugacity coefficients. In the case of vapour phase, $z_i = y_i$ and v is the vapour molar volume, whereas for the liquid phase, $z_i = x_i$ and v is the liquid molar volume. The ratio of the two fugacity coefficients yields the K value under the conditions of interest.

Calculation of Activity Coefficients

Activity coefficients, γ_i are generally calculated by differentiation of the excess Gibbs energy g^E :

$$RT \ln \gamma_i = \left(\frac{\partial n g^E}{\partial n_i} \right)_{T, P, n_j} \quad [46]$$

A number of expressions have been proposed for g^E as a function of composition. Some of the more popular of these are outlined below.

Margules Equation

The Margules equation is one of the simplest expressions for the molar excess Gibbs energy. For a binary solution:

$$\frac{g^E}{RT} = x_1 x_2 (A_{21} x_1 + A_{12} x_2) \quad [47]$$

where A_{12} and A_{21} are binary parameters dependent on temperature, but not on the composition. The Margules activity coefficients in a binary mixture are obtained by differentiation of eqn [47] and are given by:

$$\ln \gamma_1 = [A_{12} + 2(A_{21} - A_{12})x_1]x_2^2 \quad [48]$$

$$\ln \gamma_2 = [A_{21} + 2(A_{12} - A_{21})x_2]x_1^2 \quad [49]$$

A_{12} and A_{21} are generally obtained by fitting VLE data. Note that the value of the activity coefficient of each component tends to unity as the mole fraction of that component goes to unity. This behaviour is inherent in all g^E models. The Margules equation works well for binary systems in which the two components are very similar in size, shape and chemical nature. Margules parameters for a large number of systems are tabulated in DECHEMA books on VLE data.

Van Laar Equation

The van Laar equation for the excess Gibbs energy may be written as:

$$\frac{g^E}{RT} = \frac{2a_{12}x_1x_2q_1q_2}{x_1q_1 + x_2q_2} \quad [50]$$

where q_1 and q_2 are the effective volumes of the two molecules and a_{12} is an interaction parameter. Differentiation according to eqn [46] leads to the following expressions for the activity coefficients:

$$\ln \gamma_1 = \frac{A_{12}}{\left[1 + \frac{A_{12}x_1}{A_{21}x_2}\right]^2} \quad [51]$$

$$\ln \gamma_2 = \frac{A_{21}}{\left[1 + \frac{A_{21}x_2}{A_{12}x_1}\right]^2} \quad [52]$$

where $A_{12} = 2q_1a_{12}$ and $A_{21} = q_2a_{12}$. As in the case of the Margules equation, the two parameters A_{12} and A_{21} are obtained by fitting VLE data. The van Laar equations have been shown to work well for a number of binary systems where the size, shape and chemical nature of the components are dissimilar, and parameters for many binary systems have been tabulated in the DECHEMA data books.

Wilson Equation

The Margules equation is based on the assumption that the ratio of species 1 to species 2 molecules surrounding any molecule is the same as the ratio of the mole fractions of species 1 and 2. A different class of g^E models has been proposed based on the assumption that, around each molecule, there is a local composition that is different from the bulk composition. The Wilson equation is such a local composition model and the Wilson excess Gibbs energy has the following form for a binary system:

$$\frac{g^E}{RT} = x_1 \ln(x_1 + \Lambda_{12}x_2) - x_2 \ln(x_2 + \Lambda_{21}x_1) \quad [53]$$

where Λ_{12} and Λ_{21} are parameters specific to the binary pair. These parameters are defined in terms of

the molar liquid volume v_i of the pure component i , and the energies of interaction λ_{ij} between the molecules i and j as follows:

$$\Lambda_{ij} = \frac{v_j}{v_i} \exp\left[-\frac{\lambda_{ij} - \lambda_{ii}}{RT}\right] \quad [54]$$

The expression for the liquid activity coefficients are:

$$\ln \gamma_1 = -\ln(x_1 + \Lambda_{12}x_2) + x_2 \left(\frac{\Lambda_{12}}{x_1 + \Lambda_{12}x_2} - \frac{\Lambda_{21}}{x_2 + \Lambda_{21}x_1} \right) \quad [55]$$

$$\ln \gamma_2 = -\ln(x_2 + \Lambda_{21}x_1) + x_1 \left(\frac{\Lambda_{21}}{x_2 + \Lambda_{21}x_1} - \frac{\Lambda_{12}}{x_1 + \Lambda_{12}x_2} \right) \quad [56]$$

The Wilson equation has two parameters Λ_{12} and Λ_{21} (or equivalently, $\lambda_{12} - \lambda_{11}$ and $\lambda_{21} - \lambda_{22}$) and is able to correlate VLE data for a wide variety of miscible systems, including those containing polar or associating components in nonpolar solvents. However, the equation is incapable of predicting liquid–liquid immiscibility in a system.

For multicomponent mixtures, the Wilson equation is written as follows:

$$\ln \gamma_k = -\ln \left[\sum_{j=1}^m x_j \Lambda_{kj} \right] + 1 - \sum_{i=1}^m \frac{x_i \Lambda_{ik}}{\sum_{j=1}^m x_j \Lambda_{ij}} \quad [57]$$

Note that only binary parameters Λ_{ij} are required to evaluate activity coefficients in multicomponent systems. These parameters are obtained by fitting VLE data for the binary pairs, and many of these parameters have been tabulated in the DECHEMA data books. Moreover, because a temperature dependence is included in eqn [54], the same binary parameters may be used over a range of temperatures (although no more than about 50 K).

NRTL Equation

The NRTL (non-random two-liquid theory) equation is also based on a local composition model for the excess Gibbs energy. However, it is applicable to miscible as well as partially miscible systems due to the inclusion of a third binary parameter in the model. The expression for the molar excess Gibbs energy is:

$$\frac{g^E}{RT} = x_1x_2 \left[\frac{\tau_{21}G_{21}}{x_1 + x_2G_{21}} + \frac{\tau_{12}G_{12}}{x_2 + x_1G_{12}} \right] \quad [58]$$

where τ_{ij} and G_{ij} are defined as:

$$G_{ij} = \exp(-\zeta_{ij}\tau_{ij}) \quad [59]$$

$$\tau_{ij} = \frac{g_{ij} - g_{ji}}{RT} \quad [60]$$

g_{ij} describes the energy of interaction between component i and j and ζ_{ij} ($=\zeta_{ji}$) is a nonrandomness parameter which is often set equal to 0.3. Thus, only two parameters τ_{ij} and τ_{ji} (or, equivalently, $g_{ij} - g_{ji}$ and $g_{ji} - g_{ii}$) are required per binary pair.

The activity coefficients expressions are as follows:

$$\ln \gamma_1 = x_2^2 \left[\tau_{21} \left(\frac{G_{21}}{x_1 + G_{21}x_2} \right)^2 + \frac{\tau_{12}G_{12}}{(x_2 + G_{12}x_1)^2} \right] \quad [61]$$

$$\ln \gamma_2 = x_1^2 \left[\tau_{12} \left(\frac{G_{12}}{x_2 + G_{12}x_1} \right)^2 + \frac{\tau_{21}G_{21}}{(x_1 + G_{21}x_2)^2} \right] \quad [62]$$

A major advantage of the NRTL equation lies in its ability to represent highly nonideal systems, particularly partially miscible systems.

For multicomponent mixtures, the liquid-phase activity coefficients are expressed as:

$$\ln \gamma_i = \frac{\sum_{j=1}^m \tau_{ji} G_{ji} x_j}{\sum_{l=1}^m G_{li} x_l} + \sum_{j=1}^m \frac{x_j G_{ij}}{\sum_{l=1}^m G_{lj} x_l} \left(\tau_{ij} - \frac{\sum_{r=1}^m x_r \tau_{rj} G_{rj}}{\sum_{l=1}^m G_{lj} x_l} \right) \quad [63]$$

As with the Wilson equation, only binary data are needed to calculate activity coefficients in multicomponent systems, and these parameters have been tabulated in the DECHEMA data books for many systems. Furthermore, because of the inclusion of the temperature in eqn [60] the parameters obtained by fitting VLE data at one temperature may be used to calculate VLE at other temperatures (within a range of about 50 K).

UNIQUAC Equation

The UNIQUAC (universal quasi-chemical theory) equation expresses the molar excess Gibbs energy as a sum of a combinatorial part and residual part.

$$g^E = g^E(\text{combinatorial}) + g^E(\text{residual}) \quad [64]$$

The combinatorial part accounts for differences in the size and shape of the molecules, whereas the residual contribution accounts for energetic interactions.

$$\frac{g^E(\text{combinatorial})}{RT} = x_1 \ln \frac{\Phi_1}{x_1} + x_2 \ln \frac{\Phi_2}{x_2} + \frac{z}{2} \left(q_1 x_1 \ln \frac{\theta_1}{\Phi_1} + q_2 x_2 \ln \frac{\theta_2}{\Phi_2} \right) \quad [65]$$

$$\frac{g^E(\text{residual})}{RT} = -q_1 x_1 \ln(\theta_1 + \theta_2 \tau_{21}) - q_2 x_2 \ln(\theta_2 + \theta_1 \tau_{12}) \quad [66]$$

where:

$$\Phi_i = \frac{x_i r_i}{\sum_j x_j r_j} \quad [67]$$

$$\theta_i = \frac{x_i q_i}{\sum_j x_j q_j} \quad [68]$$

$$\tau_{ji} = \exp \left(-\frac{a_{ji}}{RT} \right) \quad [69]$$

In eqn [65] z is a coordination number ($=10$ usually), Φ_i are volume fractions, and θ_i are surface area fractions for component i . The volume and surface area parameters r_i and q_i can be evaluated from pure component molecular structure information and are tabulated in the DECHEMA data books. Thus, there are two binary parameters a_{ij} and a_{ji} in the UNIQUAC model and these are found by fitting binary VLE data. The activity coefficient expressions become:

$$\ln \gamma_1 = \ln \frac{\Phi_1}{x_1} + \left(\frac{z}{2} \right) q_1 \ln \frac{\theta_1}{\Phi_1} + \Phi_2 \left(l_1 - \frac{r_1}{r_2} l_2 \right) - q_1 \ln(\theta_1 + \theta_2 \tau_{21}) + \theta_2 q_1 \left(\frac{\tau_{21}}{\theta_1 + \theta_2 \tau_{21}} - \frac{\tau_{12}}{\theta_2 + \theta_1 \tau_{12}} \right) \quad [70]$$

$$\ln \gamma_2 = \ln \frac{\Phi_2}{x_2} + \left(\frac{z}{2} \right) q_2 \ln \frac{\theta_2}{\Phi_2} + \Phi_1 \left(l_2 - \frac{r_2}{r_1} l_1 \right) - q_2 \ln(\theta_2 + \theta_1 \tau_{12}) + \theta_1 q_2 \left(\frac{\tau_{12}}{\theta_2 + \theta_1 \tau_{12}} - \frac{\tau_{21}}{\theta_1 + \theta_2 \tau_{21}} \right) \quad [71]$$

where:

$$l_i = \left(\frac{z}{2} \right) (r_i - q_i) - (r_i - 1) \quad [72]$$

The UNIQUAC equation is applicable to a wide range of systems, including partially miscible systems.

For multicomponent systems, the UNIQUAC equation becomes:

$$\ln \gamma_i = \ln \frac{\Phi_i}{x_i} + \frac{z}{2} q_i \ln \frac{\theta_i}{\Phi_i} + l_i - \frac{\Phi_i}{x_i} \sum_{j=1}^m x_j l_j - q_i \ln \left(\sum_{j=1}^m \theta_j \tau_{ji} \right) + q_i - q_i \sum_{j=1}^m \frac{\theta_j \tau_{ij}}{\sum_{k=1}^m \theta_k \tau_{kj}} \quad [73]$$

Once again, only pure component and binary data are needed to calculate the parameters. UNIQUAC parameters for over 6000 binary systems have been tabulated in the DECHEMA data series on VLE.

UNIFAC Group Contribution Method

When values of Margules, van Laar, Wilson, NRTL or UNIQUAC parameters are not available in the literature, or when no VLE data for the system of interest have been measured, the UNIFAC (UNIQUAC functional group activity coefficients) method may be used to estimate activity coefficients. The UNIFAC method is a group contribution technique for the estimation of the parameters a_{mn} of the excess Gibbs energy model. The method expresses the molar excess Gibbs energy as a sum of a combinatorial part and a residual part and uses the same combinatorial part as the UNIQUAC equation. In terms of the activity coefficient:

$$\ln \gamma_i = \ln \gamma_i^C + \ln \gamma_i^R \quad [74]$$

$$\ln \gamma_i^C = \ln \frac{\Phi_i}{x_i} + \left(\frac{z}{2} \right) q_i \ln \frac{\theta_i}{\Phi_i} + \Phi_i \left(l_i - \frac{r_i}{r_j} l_j \right) \quad [75]$$

$$r_i = \sum_k v_{ki} R_k \quad [76]$$

$$q_i = \sum_k v_{ki} Q_k \quad [77]$$

The group R_k , and the group area Q_k have been tabulated for a large number of groups. v_{ki} is the number of groups of k kind in molecule i .

The residual contribution is expressed as follows:

$$\ln \gamma_i^R = \sum_k Q_k (\ln \Gamma_k - \ln \Gamma_k^{(i)}) \quad [78]$$

$$\ln \Gamma_k = Q_k (1 - \ln E_k - F_k) \quad [79]$$

$$\ln \Gamma_k^{(i)} = Q_k^{(i)} (1 - \ln E_k^{(i)} - F_k^{(i)}) \quad [80]$$

$$E_k = \theta_1 \psi_{1k} + \theta_2 \psi_{2k} + \theta_3 \psi_{3k} + \dots \quad [81]$$

$$F_k = \frac{\theta_1 \psi_{k1}}{E_1} + \frac{\theta_2 \psi_{k2}}{E_2} + \frac{\theta_3 \psi_{k3}}{E_3} + \dots \quad [82]$$

$$\theta_m = \frac{X_m Q_m}{\sum_n X_n Q_n} \quad [83]$$

$$\psi_{mn} = \exp \left(- \frac{a_{mn}}{T} \right) \quad [84]$$

$$X_m = \frac{\sum_i x_i v_{mi}}{\sum_i \left(x_i \sum_k v_{ki} \right)} \quad [85]$$

Since the group volume parameters R_k and the group area parameters Q_k are known, the only unknowns in the UNIFAC equations are the group interaction parameters a_{mn} and a_{nm} . These have been tabulated for a large number of groups. Moreover, updated parameters are published regularly in the literature. The UNIFAC method has been successfully applied to a wide variety of binary and multicomponent systems.

Examples of Use

Subcritical Vapour–Liquid Equilibria

Figure 4 shows the P - x - y behaviour of the methanol–water system at 313 K calculated using the activity coefficient approach. Activity coefficients were obtained from the Wilson equation using parameters $\Lambda_{12} = -449.3$ and $\Lambda_{21} = -835.9$ reported in DECHEMA data books. Fugacity coefficients in the vapour phase were assumed to be equal to 1.0. Note that the Wilson parameters were obtained by fitting the data, and therefore reproduce the experimental

Figure 4 The P - x - y behaviour of methanol–water at 313 K correlated with the Wilson equation.

Figure 5 The P - x - y behaviour of methanol-water at 373 K predicted using Wilson equation constants obtained at 313 K.

data (open circles) reasonably well in this system. Figure 5 shows that when the same parameters are used to calculate VLE data for methanol-water at 373 K, good agreement is obtained with experimental data.

Figure 6 shows the P - x - y behaviour at 313 K of the same system correlated using the Patel-Teja equation of state. Two k_{ij} values were required to correlate the data ($k_{12} = -0.0923$ and $k_{21} = 0.0748$) and, in general, excellent agreement was obtained between calculated and experimental values. Moreover, the equation of state was successful in predicting data at

Figure 6 The P - x - y behaviour of methanol-water at 313 K correlated with the Patel-Teja equation.

Figure 7 The P - x - y behaviour of methanol-water at 373 K predicted with Patel-Teja equation using binary parameters obtained at 313 K.

373 K using the same values of the k_{ij} parameters, as shown in Figure 7.

Supercritical Vapour-Liquid Equilibria

Figure 8 shows the P - x - y behaviour of the carbon dioxide-propane system at 328 K predicted using the equation of state approach with the Patel-Teja equation of state. The two binary interaction

Figure 8 The P - x - y behaviour of CO_2 -propane mixtures at 328 K predicted using the Patel-Teja equation of state with binary parameters obtained from data at 244 K.

Figure 9 The P - x - y behaviour of methane- n -butane mixtures at 344 K predicted using the Patel-Teja equation of state with binary parameters obtained from data at 186 K.

parameters ($k_{12} = 0.143$ and $k_{21} = 0.121$) were obtained by fitting data at a much lower temperature of 244 K. The predictions are in excellent agreement with experiment, even though the extrapolation is to a temperature that is above the critical temperature of carbon dioxide (304 K). A similar extrapolation using the Patel-Teja equation of state is shown in Figure 9 where VLE in the methane- n -butane system at 344 K have been predicted using binary parameters ($k_{12} = 0.021$ and $k_{21} = 0.002$) obtained at 186 K. Note that the extrapolation is carried out to a temperature that is well above the critical temperature of methane (190 K). Finally, it should be added that the activity coefficient approach described above cannot be used to correlate or predict supercritical VLE behaviour.

ELECTROPHORESIS

Agarose Gels

Development

Agarose is a uniquely nonadhesive hydrocolloid that has found many uses in the separation sciences

following Araki's preparation of it in 1937 as an apparently sulfate-free component distinct from the sulfate-rich agaropeptin in agar. Agar and many of the other hydrocolloids derived from certain species of seaweed had been used mainly in food preparation dating back to the seventeenth century in Japan. Agar was introduced as a medium for immunoelectrophoresis by Grabar and Williams in 1953, and the original technique is occasionally used today. Citrated agar electrophoresis is the current principal method for identification of haemoglobin variants. Agar was

applied by Polson in 1961 for chromatographic separations based on molecular sieving, following which its use gradually gave way to agarose beginning with Hjertén. A word-search of the Medline abstracts indicates that the number of papers per year employing agarose electrophoresis did not surpass agar electrophoresis until 1976.

The sulfate content of grades of agarose supplied for laboratory use is generally below 0.12% compared to 4% in agarpectin (see Armisen, 1997). The ease with which agarose can be cast into gels without additives or cross-linking agents and its inertness towards interacting with proteins and nucleic acids are the principal reasons for its popularity as a separation medium. All that is needed to prepare gels is to dissolve the agarose powder by careful heating to boiling or near boiling temperatures, and let the clear solution cool. Gelation proceeds spontaneously and completely as the solution cools. In addition to the simplicity of gel casting with agarose and its inertness towards interacting with proteins and nucleic acids, it offers many other advantages as a separation medium, such as easy sample recovery, nontoxicity, and amenability to cast and use it in an open faced format. The latter option underlies its unique applicability to numerous immunoelectrophoretic procedures. Agarose is very porous compared to polyacrylamide, and that limits its suitability in unmodified form for sieving-based separations of proteins with molecular masses below 60 kDa. On the other hand, its high permeability makes it, again, superior to polyacrylamide for immunochemical studies.

Properties of Agarose Gels

Chemically, agarose is a polysaccharide composed of alternating D- and L-galactose biose (agarobiose) units in chains that are on the order of 400 agarobiose units in length, ~120 kDa. Rees and Arnott each characterized the gelation as proceeding initially through pairing of the 120 kDa chains into 0.8–1.4 nm thickness double helical coils, followed by lateral coalescence of the helical dimers into thick protofibrils with average thickness of the order of 24 nm, although the number of helical dimers can range from 5 to 5000. By contrast, conventional polyacrylamide gels have fibre thickness of only 0.4 nm. Gelation occurs as the thick protofibrils interlink at their loosely coiled ends into a net-like matrix (Figure 1). The gels are translucent because of light scattering by the thick fibrils, but become transparent on drying. The ability to form thick, strong fibres enables agarose to form gels at concentrations down to 0.2% as utilized in studies by Serwer. The incorporation of

Figure 1 Depiction of structure of the agarose biose unit and the structure of interlocking aggregates of coiled coil dimers of agarose chains based on electron microscopy and X-ray diffraction. (Reproduced with permission from Westermeier, 1997.)

the agarose into thick rather than thin fibres makes the gels highly porous at concentrations up to 6%, the limit to which agarose can be dissolved without resorting to autoclave temperatures. Concentrations up to 16% can be reached by autoclaving.

The high porosity makes agarose superior to polyacrylamide for separation of large proteins, polypeptides, complexes with size ranging from 100 kDa to several megadaltons, and for DNA fragments ranging from 1000 to 23 000 bp. In the interest of retaining the gel casting simplicity of agarose while enhancing its sieving capacity, nonsupercoiling hydroxyalkylated agarose derivatives have been developed which, according to Chrambach, have fibre thicknesses of the order of 0.8 nm, approaching polyacrylamide, but have gel strengths that are low compared to unmodified agarose. Recently, blends of agarose derivatives have been formulated which have improved strength.

The sulfate present in most commercial agarose induces a slight electroendosmosis (EEO) during electrophoresis. Electroendosmosis is the flow of buffer through the gel. In effect it arises because the negatively charged sulfate groups in the matrix cannot move towards the anode which results in a compensatory pumping of buffer to the cathode. The slight effect on mobility of proteins is usually of little consequence; however, it can have pronounced effects on mobilities of buffer boundaries in discontinuous buffer systems used for sharpening bands in the applied samples. It can also induce syneresis and collapse of gels with discontinuous buffer systems due to unequal electroendosmosis across the buffer boundaries. Thus, some of the numerous buffer systems that have been described in the computer output by Jovin for polyacrylamide gels do not work well with agarose gels. Many do, nevertheless. The zero-EEO agarose which is used for isoelectric focusing has its electroendosmotic tendency neutralized by charge-balancing with electropositive groups. The additives in some

zero-EEO agaroses contribute to background staining.

The gelation of agarose depends entirely on hydrogen bonding, and is inhibited by chaotropic agents such as concentrated (~20%) glycerine or urea. Although the high concentrations of these substances usually used in biochemical procedures can block the gelation, they do not appreciably affect gels once solidified. As with all electrophoresis, concentrated ionic chaotropes such as guanidine-HCl and KSCN which are used as protein solubilizing and denaturing agents should be removed and replaced with either urea or SDS prior to electrophoresis. Since the aggregation of agarose is fully reversible, gels can melt under high current. Also, agarose gels are compressible, and tend to drop out of vertical electrophoresis cells unless supported. The ability using weights to mechanically compress agarose gels to within a few per cent of original thickness can be used to advantage. Gels containing more than 2.5% agarose will rehydrate to the original thickness within a fraction of an hour, but gels with 1% or less agarose have a greatly reduced tendency to rehydrate.

Agarose Derivatives

Numerous agarose derivatives have been described for affinity chromatography where addition of charged groups is not critical. All derivatives prepared for electrophoresis involve modifications not imparting electrical charges. As indicated earlier, hydroxyethylated (FMC BioProducts) and hydroxymethylated agarose (Hispanagar, SA) are low melting derivatives which form gels with thin fibres for enhanced sieving. These low melting agaroses have been used to impart sieving during capillary electrophoresis. Allylglycidyl agarose, a very low melting derivative, is frequently used in place of bis-acrylamide for cross-linking acrylamide into stronger gels. All of the commercially available derivatives yield gels with low melting points. That is because the agarose is derivatized in a molten state. As we learned in studies on alkylation of agarose with either glycidol or allylglycidyl ether from preparing glyoxyl agarose and its analogues, the hydroxyl groups involved in the hydrogen bonding functioning in gelation are protected during derivatization of the agarose in the gel state, and the derivatized agarose gel retains much of its original melting and gelling characteristics.

Glyoxyl agarose (oxidized glyceryl agarose) has acetaldehyde substituent groups which can be utilized to form Schiff's base linkages with protein amino groups. At pH < 8.5, these Schiff's base linkages are too dissociated to retard electrophoresis of the pro-

teins. Once separated on the glyoxyl agarose gel, the proteins can be driven to bind to it, either reversibly by immersion in pH 10 buffer to suppress dissociation of the Schiff's base linkages or by immersion in buffer containing sodium cyanoborohydride which rapidly and specifically drives alkylation of amino groups of the protein with the aldehyde groups in the gel matrix. This functionality enables the gel to be used sequentially and repetitively as a protein-separating and immobilizing medium. It can also fix small peptides containing at least a single amino group, but does not fix nucleotides. By compositing it with a removable polyacrylamide filler, it can be used for separations over any molecular weight range.

Agarose/Polyacrylamide Composites

These media were constructed initially to provide a supporting agarose matrix for polyacrylamide at concentrations below 3–4% which do not form firm gels. The combinations can yield exceedingly strong gels (Figure 2) and provide facility to achieve a wide range of sieving characteristics. As described by Peacock and Dingman in 1968, strong gels are obtained only when formulated to allow the agarose to gel before the acrylamide polymerizes. By using either non-cross-linked polyacrylamide or cross-linkers such as alkali or periodate degradable 1,2-dihydroxyethylene-bis-acrylamide instead of the usual bis-acrylamide, the poorly-permeable acrylamide filler can be removed leaving a highly permeable agarose matrix to allow direct immunochemical characterization of the fixed components of the electropherogram.

Electrophoresis

Initial applications of agarose electrophoresis focused heavily on diagnostic separations of plasma proteins, particularly lipoproteins, with great improvement over results obtained with paper or with starch which had been used earlier. Straight analytical separations were followed by more definitive immunoelectrophoretic protein identifications. These separations were usually applied to native, undenatured proteins. Following introduction in 1967 of sodium dodecyl sulfate (SDS) by Shapiro, Viñuela and Miazal as a carrier enabling polyacrylamide-based separation of proteins according to molecular weight by imposing overwhelming negative charge over the original and by denaturing conformational differences between proteins, the practice was widely adopted as a rapid means for separating large-sized proteins on agarose. The converse approach of separating proteins according to differences in isoelectric points

Figure 2 Demonstration of the strength of agarose/polyacrylamide composite gels. (Reproduced with permission from Shainoff, 1993.)

independent of molecular size by establishing a pH gradient across the gel was demonstrated in 1969 by Vesterberg, but a decade passed before the development of zero-EEO agarose enabled this separation method to be used with agarose.

Equipment and Buffer Systems

Agarose gels are usually used for electrophoresis on a horizontal platen on which the gels are placed between anodic and cathodic electrode chambers filled with buffer and connected to the gel with buffer-filled wicks. Except for the usual need to purchase a platen that can be cooled with circulating water, this is a simple arrangement that is easily set up, largely because of the ease with which agarose gels are cast either open faced or in cassettes consisting of two spacer-separated glass plates which can be separated from the gel because the gel is nonadherent. The use of wicks can be troublesome, because voltage is lost across them, and this produces much of the heating and vapour condensation in the chamber. Voltage drop across the gels must be gauged directly from the gel rather than the power supply. Condensation of vapour on the gel is easily prevented by simply laying a vapour barrier, usually GelBond® (FMC Bio-Products), over the gel. For nucleic acid electrophoresis the use of wicks has been obviated by a technique known as 'submarine' electrophoresis in which the gel is laid into a buffer-filled platform connecting the electrode chambers. The submarine mode is usually not applicable to protein electrophoresis because proteins tend to diffuse into the surrounding buffer, while nucleic acids which have very low diffusion

constants migrate almost entirely due to the applied voltage with little diffusion. Running agarose gels in vertical format with electrode chambers directly above and below the gel-containing cassette, as generally used with polyacrylamide gels, is seldom recommended because of the tendency of agarose to synerese and slip out of the cassette, a problem that can be prevented by use of etched rather than clear glass for the cassette. Slipping can also be prevented by partially immersing the cassette into dilute 0.5% agarose, and letting the agarose drain and dry before pouring the running gel.

Sample applications into agarose gels were initially made by either cutting or punching a slot or hole to receive the solution. This approach continues to be used with nucleic acids which form sharp bands as they migrate out of the nonrestrictive sample solution into the migration-restrictive gel, but comparatively little band sharpening occurs with proteins which easily permeate the gels. Further, the wells induce band distortions of proteins due: (i) to partial permeation into the sides of the wells prior to electrophoresis; and (ii) to uneven voltage drops across the wells. Because of the ease with which solutions can be imbibed into agarose following a temporary compression with blotting paper, samples can be drawn into the gels in nicely demarcated bands through a 'sample application foil', thin plastic overlays with slots through which the samples are drawn into the gels. Large samples need band-sharpening which can be achieved either mechanically by temporarily overlaying a dialysis membrane and thick gel to produce a sharp voltage drop near the origin, or by use of discontinuous buffer systems.

A method for sharpening bands at the beginning of runs at the outset of electrophoresis was devised by Ornstein and Davis using a discontinuous buffer system, 'disc electrophoresis', in which proteins and all but common electrolytes stack in hypersharp bands at the boundary between initial buffer ions producing low conductivity and secondary buffer ions producing high conductivity with a common counter ion. The discontinuous buffer systems worked predictably with over 7000 computer generated buffer systems based on the pK_a values of the leading and trailing buffering ions, as far as known, with polyacrylamide gels which produce no EEO, but only a few have been tested and found to yield operable systems with agarose, as already noted.

The ability to run agarose gels horizontally in a virtual open-faced format is its real advantage. That enables the gels to be cut and manipulated post-electrophoresis to conduct secondary electrophoretic operations with it. This facility has made it the usual medium for immunoelectrophoretic analyses.

Staining

With the exception of silver staining, all commonly used staining methods (Coomassie-based, fluorescent, chemiluminescent, and colloidal-type) work well with agarose, colloidal Coomassie being one of the fastest. An important consideration is to minimize exposure to acid which hydrolytically weakens the gel. Unlike polyacrylamide, agarose gels can be directly immunostained as illustrated (Figure 3), but the antibodies should be free of large entrapable aggregates.

Immunoelectrophoresis

These methods are based on immune-precipitate (precipitin) formation at antigen/antibody equivalence, analogous to Ouchterlony immunodiffusional analyses in which antibody and antigen placed in separate wells in agar(ose) form precipitin arcs in the gel at position(s) depending on levels of antigen and antibody in the wells. In the method of Grabar and Williams the proteins under analysis are separated on agar gels, then lateral slots are cut approximately 8 mm to each side of the gel to accommodate antibody. After a day lateral diffusion of the protein bands towards the counter-diffusing antibody one or more precipitin arcs will form in the gel depending on the antibody and antigen heterogeneity. Quantitation of antigen/antibody by this method requires considerable effort and multiple runs. A simpler approach to quantitation was devised by Laurell, using a method known as 'rocket immunoelectrophoresis'.

Figure 3 (See Colour Plate 39). Direct dual immunostaining of a polyacrylamide/glyoxyl-agarose composite gel to profile fibrinogen γ -chain (grey), α -chain (amber) cross-linking and hybrid α/γ -chain (umber) cross-linking by plasma transglutaminase (right lane), and the chain composition of plasma fibrinogen. The illustration depicts sieving equivalent to a regular polyacrylamide gel, and subsequent rendering of the gel for antibody permeation by removing the polyacrylamide. (Reproduced with permission from Shainoff *et al.*, 1991, *Journal of Biological Chemistry* 266: 6429.)

In the method of Laurell, the gel is poured with antibody added to it at 56°C, and wells are punched in the solidified gel to accommodate the antigen solution. As the antigen moves by electrophoresis out of the well it sweeps soluble immune complexes along with it in a comet-shaped profile until the antigen/antibody levels become equivalent, whereupon the comet-shaped precipitin arc comes to a virtual stop because the antibodies themselves do not migrate at around pH 8.6. The area contained within the arc is usually directly proportional to the antigen level. Because of the ease with which agarose gels can be cut and filled with interposed gels open-faced, this technique is amenable to a myriad of variations, as described by Axelsen and associates.

In one variation of the Laurell method, called crossed immunoelectrophoresis, the proteins are subjected to pre-electrophoresis, and antibody-containing agarose is cast around a strip of the gel. Then, in a crossed electrophoresis the antigens are transferred out of the primary gel into the antibody where they form rocket(s) in line with their initial position. The technique is 'found' useful for quantifying multiple antigens and variant forms of an antigen. If the initial gel contains SDS, it should be quenched by adding nonionic detergent such as Lubrol® to the antibody-containing gel. In the event that the protein becomes insoluble when stripped of SDS, initially it can be fixed, then probed with charge-enhanced carbamylated primary antibody. Retained antibody is measured by electrophoresis into secondary antibody, as illustrated in **Figure 4**. Use of secondary antibodies is also essential when using monoclonal IgG antibodies as primary probes, because these monoclonal antibodies do not form immunoprecipitates on their own unless the epitope is multiply expressed in the antigen.

Direct Immunoprobing

Because of the permeability of agarose gels to antibody it is possible to probe electropherograms directly. Direct immunoprecipitation within the gel is seldom used because of uncertainties of levels or antibody required for substantial precipitation of un-

known levels of antigen. The proteins are usually fixed or immobilized, and probed by imbibing labelled antibody into and out of the gel. If secondary antibodies are to be used to report retention of the primary antibody, the primary antibody should in turn be fixed before the secondary probing to avoid dissociative losses of the primary during the secondary probing which takes periods of the order of an hour. Glyoxyl agarose was developed to enable these fixations by chemical immobilization.

Blotting

This widely used procedure involves transfer of components out of the gel on to a blotting membrane to immobilize them for immunostaining or compositional analysis on an open-faced surface. It is an essential means for probing reactivities of components separated on polyacrylamide because of the low permeability of the gel. Much uncertainty attends this 'blotting', because the transfers are incomplete, and frequently nil with high molecular mass proteins. These proteins not only transfer slowly, but often precipitate within the gel as SDS transfers away from them. Also, very low molecular mass peptides fail to be retained by the blotting membrane.

While blotting from polyacrylamide gels is usually effected by crossed electrophoresis, the transfers out of agarose gels are more simply effected by either compressing them against the membrane supported on filter paper stacks (a method that yields only partial transfer), or by light vacuum suctioning of buffer through the gel on to the membrane supported on a 'gel drier'. However, when SDS is present it must either be quenched by a prior 15 min immersion in buffer containing 1–2% nonionic detergent, or precipitated by immersing the gel in 0.1 M KCl.

Affinity Electrophoresis

These methods use specific ligands, either added to the buffer or immobilized on the gel matrix, to induce shifts in mobilities or apparent concentrations of target proteins. Again, ability to work with open-faced gels to interpose ligand-rich zones makes it an ideal medium for these procedures, as devised with numerous examples from crossed immunoelectrophoresis. With glyoxyl agarose a ligand containing at least a single amino group can be imbibed into the gel through a mask and fixed in place.

Conclusion

Equipment and supplies for general electrophoresis on agarose have undergone little change over the last

Figure 4 Crossed immunoelectrophoresis to profile plasma fibrinogen derivatives in plasma by: (i) probing the electropherogram with primary antifibrinogen antibodies; and (ii) measuring the retained antibody by displacing to form rockets in secondary gel containing anti-IgG antibodies, with standards for the IgG forming the left- and right-most peaks. This approach was made necessary because insolubility of fibrinogen and its high molecular mass derivatives, once denatured by SDS, cannot be transferred out of the primary electropherogram to form rockets directly. (Reproduced from Dardik *et al.*, 1989, *Cleveland Clinical Journal of Medicine* 56: 451.)

two decades. Improved imaging systems and labelling agents for high sensitivity detection and linear quantitation by fluorescence and chemiluminescence offer attractive alternatives to immunostaining and the use of radioisotopes, and have made rapid automated nucleic acid sequencing possible. Except for those involved in nucleic acid work, few laboratories perform electrophoresis on agarose on a day-to-day basis; thus, accessories for many techniques such as immunoelectrophoresis have been dropped by suppliers. There may be a revival because of growing interest in several proteins which are not separable in polyacrylamide matrices, von Willebrand factor multimers for diagnosis of certain types of von Willebrand's disease, and high molecular mass derivatives of fibrinogen as markers of vascular disease.

More efficient cooling and thermal control would allow the application of much higher voltages for high performance agarose electrophoresis above the present limitations imposed by gel meltdown. By using an apparatus in which the gel is enveloped with a membranous bladder for cooling, von Willebrand factor multimers can be separated in 20 min runs producing resolution superior to that obtained with the usual overnight runs widely used through the 1990s.

Precast polyacrylamide gels have become popular, and precast agarose gels are available for submarine electrophoresis. Compressibility of agarose is the principal detriment to precasts for other modes of electrophoresis. Agarose/polyacrylamide composites would not be subject to that drawback, and would probably be marketable in precast form because they offer advantages and are not as easily constructed as gels of agarose itself.

Summarily, agarose gels are simple to construct. They are highly porous and ideal for separating high

molecular mass proteins and nucleic acids, and can be modified or composited to extend their utility.

Introduction

The migration of charged particles under the influence of an electric field was discovered and characterized theoretically more than 100 years ago by Kolrausch *et al.* Foreseeing the possibility of separation of charged species through the application of a voltage, the term 'electrophoresis' was coined soon after. However, early attempts to use electrophoresis as an analytical tool were persistently frustrated by the existence of Joule heating, which acts to discount the electrophoretic effect. Thus a way of combatting the thermal effect during the electrophoretic process was needed. By 1950s, Tiselius *et al.* found that a variety of substances such as agarose and polymeric gels could serve as stabilizing agents in electrophoretic analysis owing to their anticonvective properties. This eventually led to the creation of slab gel electrophoresis, which has become a fundamental technique for the study of proteins, DNA fragments and other biomacromolecules in life sciences and biotechnology. Notwithstanding its great success, slab gel electrophoresis has its drawbacks with respect to speed and automation when compared with contemporary chromatographic techniques such as high performance liquid chromatography (HPLC).

A straightforward way to speed up an electrophoretic separation process is to apply higher electric fields, and this necessitates systems able to release the heat generated more efficiently. Electrophoresis with a tube as a separation channel is hence an attractive choice since the desired surface-to-volume ratio can be achieved by simply reducing the tube radius. Performing electrophoresis based on the tube format has an added advantage in that simultaneous detection may be implemented in a way analogous to HPLC, thus rendering the entire procedure fast and automatic. Running electrophoresis with a tube configuration was initiated by Hjerten as early as the 1960s, and further attempted by Virtanen *et al.* and Mikkers *et al.* in 1970s. During this period, the adopted inner diameters of tubes were in the range of 0.2–3 mm, and thermal effects confined the applied voltage to around 1000–2000 V, which was of the same order as in typical slab gel electrophoresis. As a consequence, despite these pioneering efforts to perform

free solution electrophoresis with in-line monitoring, the full potential with respect to column performance was not yet attained. Also, complexity in instrumental design deterred follow-up by ordinary electrophoresis practitioners.

A milestone for column-based electrophoresis was set in the early 1980s, when Jorgenson *et al.* introduced capillary zone electrophoresis (CZE) with on-column optical detection. They found that with the inner diameter of the capillaries scaled down to 80 μm , voltages as high as 30 kV could be applied without incurring overheating problems. Thus the separation time for most charged species, from small molecules to macromolecules, was shortened to less than 30 min, which is comparable to modern chromatographic methods. For the first time outstanding column efficiencies of several hundred thousand plates was routinely obtained. The unprecedented performance, relatively simple instrumentation, concurrent with the widespread availability of fused silica capillary columns by the mid-1980s quickly aroused the interests of both electrophoresis practitioners and chromatographers, thus making capillary electrophoresis (CE) one of the most exciting research areas. Today, it has become an indispensable branch of modern separation science. The powerful separation ability of CE was exemplified in an early electropherogram concerning the resolution of derivatized peptides originated from egg white lysozyme (Figure 1).

This article serves as an introduction to CE. It covers the basic principles, various aspects of instrumentation, separation modes and major applications. Some future trends of CE are discussed in the final section.

Fundamentals

Electrophoretic Migration of Ions

The uniform motion of an ion under an electric field can be recognized as a result of balancing electromotive and frictional forces of the ion in solution:

$$qE = 6\pi r\eta u \quad [1]$$

where q is the effective charge of the ion concerned, E is electric field, while r is the ion's Stokes radius, η is the dynamic viscosity of the solution, and u is the linear velocity of the ion. The important parameter, electrophoretic mobility (μ), is defined as the ion's

Figure 1 Capillary zone electrophoresis separation of fluor-escamine-labelled peptides obtained from a tryptic digest of reduced and carboxymethylated egg white lysozyme. (Adapted with permission from Jorgenson JW and Lukacs KD (1981) Zone electrophoresis in open-tubular glass capillaries: preliminary data on performance. *Journal of High Resolution Chromatography and Chromatographic Communications* 4: 230–231.)

linear velocity per unit of electric field:

$$\mu = \frac{u}{E} = \frac{q}{6\pi r\eta} \quad [2]$$

From eqn [2], it can be seen that the ion's effective charge, its size and the viscosity of the solution decide ionic mobility. Thus in a given system ionic mobility is an intrinsic property of an ion. Usually ionic mobility cannot be directly derived from eqn [2], as the parameters are not easily accessible quantities. Instead it can be measured based on relevant experimental data, i.e. how long an ion takes to travel through a certain distance under a definite electric field, as follows:

$$\mu = \frac{u}{E} = \frac{L_{\text{eff}}}{t_m} \times \frac{1}{E} = \frac{L_{\text{eff}}}{t_m} \times \frac{1}{V/L_{\text{tot}}} = \frac{L_{\text{eff}} \times L_{\text{tot}}}{V \times t_m} \quad [3]$$

where L_{eff} and L_{tot} are the effective migration length (from inlet to detection window) and total migration length, respectively, V is the applied voltage, and t_m is the migration time of the ion. For a CE system operated under a constant voltage, L_{eff} , L_{tot} and V are all

fixed. Hence electrophoretic mobility, the inherent attribute of an ion is directly reflected by its migration time. This provides the theoretical basis of using migration time as a means of identifying an ion in CE.

Electroosmotic Flow (EOF)

Electroosmosis is a fundamental electrokinetic effect involving movement of the bulk solution against a charged solid surface under the influence of an electric field. In the case of CE, the capillary inner wall usually carries negative charges due to the deprotonation of silanol groups. For the part of the liquid adjacent to the capillary wall, build-up of cations takes place to counterbalance the negative charges on the capillary surface. According to Stern's double layer model the solution containing net cations can be divided into two regions, namely a rigid layer and a diffuse double layer. The rigid layer is immediately adjacent to the capillary wall, so the cations within it are largely immobilized owing to the strong electrostatic interaction with the wall. The diffuse layer is slightly away from the wall, hence the cations inside are mobile. Upon the application of a voltage, these cations together with their surrounding hydrating water will migrate towards the cathode. The cohesive nature of water causes the whole solution inside the capillary to be dragged forward, generating a net flow across the capillary. This is named the electroosmotic flow (EOF). The magnitude of the EOF can be described via the Helmholtz equation:

$$\mu_{\text{eo}} = \frac{\epsilon \zeta}{4\pi\eta} \quad [4]$$

where ϵ is the dielectric constant of the buffer solution, ζ is the zeta-potential across the diffuse layer, and η is the viscosity of the electrolyte. Unlike conventional electrophoresis where EOF is regarded as unfavourable and thus usually suppressed, in CE it has several important positive implications.

First, the existence of an EOF offers a simple and highly efficient way of driving a separation system. The zeta-potential is uniformly distributed within an extremely narrow cylindrical region along the whole capillary so the bulk electrolyte solution is pumped out of the capillary with virtually no pressure drop (Figure 2). A 'plug-like' flow is obtained, which subsequently contributes to high column performance. This is advantageous over the conventional pumping methods such as in HPLC, where the pressure-based flow always introduces a parabolic profile thus adding to the loss of column efficiency.

Figure 2 The generation of electroosmotic flow (EOF) in a silica capillary.

Second, the presence of EOF affects the apparent mobilities of ions (**Figure 3**). In any electrophoretic separation system where EOF is not fully suppressed, the observed mobility of a charged species will be the resultant of its effective electrophoretic mobility and EOF:

$$\mu_{\text{obs}} = \mu_{\text{ep}} + \mu_{\text{eo}} \quad [5]$$

Under normal conditions, with EOF directed towards the cathode, obviously cations will be accelerated, while anions will be decelerated. If the magnitude of the EOF exceeds the mobilities of the anions, the anions will be swept towards the detection side, thus allowing the simultaneous analysis of cationic and anionic species. As the magnitude and direction of EOF will affect how long the analytes stay inside the separation capillary, manipulation of EOF often becomes a core issue for effecting a satisfactory resolution. Since the formation of EOF involves two phases (capillary wall and running buffer), any modification to their chemistries will bring about a change in EOF.

Causes of Band Broadening

As in a chromatographic process, in electrophoresis it is necessary to contain the ionic species within narrow bands while creating sufficient mobility differences. How narrow a band is depends not only on the various dispersive factors inherent to the electrophoretic process, but also on how well the whole process is performed. The common causes of band

Figure 3 Effect of EOF on the apparent mobilities of anions and cations.

broadening in CE include longitudinal diffusion, injection-related volume overloading, thermal effects, electrodispersion, wall adsorption, etc. These band broadening mechanisms are deemed to be random and independent events, so that the concept of summation of variances can be used to evaluate the contributions of individual factors to the overall band broadening effect, that is:

$$\sigma_{\text{tot}}^2 = \sigma_{\text{diff}}^2 + \sigma_{\text{inj}}^2 + \sigma_{\text{therm}}^2 + \sigma_{\text{wall}}^2 + \sigma_{\text{electr}}^2 + \sigma_{\text{other}}^2 \quad [6]$$

A brief description of these band broadening factors is given below.

Longitudinal diffusion In the course of electrophoretic transportation of an analyte band along the capillary, the sample molecules will inevitably have a tendency to enter the surrounding buffer solution because of the apparent concentration difference, leading to a wider and more dilute sample band. According to Einstein's diffusion equation, band dispersion due to longitudinal diffusion is a function of diffusion coefficient and time:

$$\sigma_{\text{diff}}^2 = 2D_m t \quad [7]$$

Under an ideal situation, longitudinal diffusion becomes the only unavoidable band broadening process. Therefore it defines the maximum attainable column efficiency in CE. Based on chromatographic theory, the maximum obtainable theoretical plates (N) can be derived as follows:

$$\begin{aligned} N &= \frac{L^2}{\sigma^2} = \frac{L^2}{2D_m t} = \frac{L^2}{2D_m \times (L/v)} \\ &= \frac{L^2}{2D_m \times [(L_{\text{eff}} \times L_{\text{tot}})/\mu V]} = \frac{\mu V}{2D_m} \end{aligned} \quad [8]$$

Thus the maximum column efficiency in CE is proportional to the mobility and voltage, while inversely proportional to the diffusion coefficient. Considering that mobilities of ions range between 10^{-4} and $10^{-3} \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$, diffusion coefficients from 10^{-7} to $10^{-5} \text{ cm}^2 \text{ s}^{-1}$, and an applied voltage up to 10^4 V , the attainable theoretical plate number would be in the order of 10^5 – 10^6 , which is much higher than any conventional HPLC approach. Eqn [8] also suggests that in principle CE should be well suited for the separation of high-mass charged particles such as biopolymers, since their diffusion coefficients are extremely low. This has been demonstrated in the most successful resolution of DNA fragments and proteins where plate numbers of 10^6 have been reached. It should be emphasized

that eqn [8] is only valid under the precondition that longitudinal diffusion plays a predominant role among the various band broadening mechanisms. In other words, to achieve the maximum column efficiency, the electrophoretic separation should be carried out in such a way that all the other potential band dispersions are curbed well below the magnitude of the longitudinal diffusion effect.

Injection related volume overload During sample injection, a finite volume of sample is placed onto the capillary. The length of this starting plug will contribute directly to the final band width. Treating the original band as rectangular in shape, the variance of this plug can be expressed by:

$$\sigma_{inj}^2 = \left(\frac{l_{inj}}{12}\right)^2 \quad [9]$$

where l_{inj} is the initial plug length. As a rule of thumb, loss of efficiency due to any extraneous dispersion factor should be kept within 10% of the maximum theoretical column efficiency. Assuming a moderate plate number in the order of 10^5 as defined by longitudinal diffusion, it can be easily estimated that the acceptable injection length should be a few millimetres. For the commonly employed capillaries with inner diameter between 50 and 75 μm , the above length is equivalent to only a few nanolitres. So it is obvious that CE's high column efficiency will pose very stringent restriction on the sample size. Any attempt to increase the injection volume in an aim to enhance detection sensitivity may result in a significant loss of column efficiency.

Thermal gradient effect An electrophoretic process is always accompanied by certain amount of thermal effects due to the passage of a current through the resistive medium (Joule heating). For a CE system, the electrical power (P) responsible for the generation of heat can be estimated through the following equation:

$$P = V \times I = \frac{V^2}{R} = \frac{V^2 \pi r^2 \lambda c}{L} \quad [10]$$

where V is the applied voltage, r and L are capillary inner radius and length, respectively, while λ and c are respectively the molar conductivity and the concentration of the electrolyte solution. While heat generation is uniform for the whole electrolyte solution, heat dissipation is apparently not: the nearer the electrolyte is to the capillary wall, the faster is the heat transferred out to the surroundings. Consequently, a temperature gradient is generally present in the radial direction of the capillary, which is

equivalent to the superimposition of a parabolic profile to the otherwise plug-like ion boundaries and bulk flow, as any temperature gradient will be translated into viscosity and mobility gradients in the solution. To minimize the influence of thermal effects on the overall column efficiency, it is imperative to limit the heat generation while maximizing the heat dissipation. In this regard, the use of narrow bore capillaries is particularly recommended because it favours the above two aspects simultaneously. According to eqn [10], for a certain CE system, heat generation may also be controlled through balancing the buffer composition and separation potential.

Wall adsorption effect The capillary surface, like most solid surfaces, never behaves in a completely inert manner to foreign compounds. In HPLC, it has been well known that peak anomalies are often the result of some specific interaction (e.g. hydrogen bonding) between the residual silanol groups and analytes. While similar adverse effects cannot be ruled out, in CE the problem is exacerbated by the fact that under a typical operation condition, the silanol groups along the wall are mostly deprotonated to give a negatively charged capillary surface. When an analyte with a positive charge travels along the capillary, the electrostatic force will tend to attract the analytes onto the wall, causing additional band broadening. This is a feature of the analysis of proteins owing to their low diffusion coefficients and multiple charge sites. Significant efforts have been made to tackle this problem, mostly through the suppression of EOF or complete reversal of the charge status of the capillary wall.

Electrodispersion Electrodispersion is the result of Ohm's law during the electrophoretic separation. It may appear in two instances. First, if the conductivity of the injection plug is larger than that of the buffer solution, an isotachopheresis effect will occur to dilute the original band till the conductivity is equal to the surrounding buffer. Second, during the separation, an analyte zone is 'submerged' into the buffer solution. Any mismatch of its mobility with its co-ions in the buffer will render the local electric field different from that in the normal running buffer. If the mobility of the sample ion is larger than that of its co-ions, then there will be a lower electrical field for the analyte zone. Thus any sample ions diffusing out of the zone will experience a higher electric field, and these ions will speed up along the migration direction. This causes the ions at the rear to re-enter the zone, whereas the ions at the front will drift away from the zone. The accumulative effect of such phenomenon is the formation of a tailing band showing a sharp

Figure 4 Mobility mismatch-induced band broadening.

trailing boundary but a broadened leading boundary. By a similar argument, if the analyte ion is of lower mobility than the co-ion, a fronting band is expected (Figure 4). The higher the sample concentration compared to the buffer concentration, the more pronounced are the nonuniformities with respect to conductivity and field strength, and eventually more severe is the band asymmetry.

From the above discussion it is obvious that, to prevent possible loss of column efficiency due to electrodispersion, the conductivity of the injection plug and the actual sample concentration should be sufficiently low. Theoretical study had shown that, to confine the electrodispersion-related band broadening at a level comparable to longitudinal diffusion, the sample concentration should be two orders below the buffer concentration. To some extent, it is the electrodispersion that limits the mass loadability of a CE system.

Instrumentation

CE can be performed with relatively simple instrumentation as depicted in Figure 5. A capillary containing an appropriate separation medium spans two buffer reservoirs, to which the high voltage power

Figure 5 Instrumental setup of a capillary electrophoresis system.

supply is connected via the platinum electrodes. Following the introduction of sample at the capillary inlet, a high voltage is applied, thus driving the analytes to travel inside the capillary with different velocities. Somewhere close to the capillary outlet, an on-line detector is installed to monitor the separation process. The resulting signals are fed to the data acquisition device, and finally the result is presented in the form of an electropherogram.

Apart from these fundamental components, commercial CE instruments are commonly equipped with some dedicated facilities, such as an autosampler, pressure regulating unit, capillary thermostating, and comprehensive supporting software. These added functions allow a sequential analysis of different samples under prespecified conditions, thus ensuring better reproducibility, accuracy and higher throughput. Two modern commercial systems are shown in Figure 6.

High Voltage Power Supply

A high voltage power source delivering stable DC potential of ± 30 kV will satisfy the requirement of most CE applications. Many power supplies offer additional features such as polarity switching, constant potential/current setting, and an interlocked

Figure 6 Commercial CE systems. (A) Bench top CE system. Photograph courtesy of Bio-Rad Laboratories. (B) Portable CE system. Photograph courtesy of CE Resources Pte. Ltd.

antieletrical shock loop. In the commercial CE instruments, the power supply is designed with digital communication capability, so that more information such as a current curve can be tracked and retrieved, and the applied voltage can be programmed.

Separation Capillary

Although capillaries made of glass or polymer (e.g. Teflon or Nylon) have found occasional application, fused silica capillaries are used predominantly in CE, largely due to their strength, flexibility and most importantly their excellent UV transparency. Usually the fused silica capillary is coated with a layer of polyimide to enhance its durability. For on-column optical detection a small segment of this coating needs to be removed to provide the detection window. The most commonly used CE capillaries have inner diameter between 20 and 75 μm , outer diameter 100–400 μm and are about 30–100 cm in length.

Sample Injection

To achieve high column efficiency and good quantitative results, sample injection must be performed in a reproducible manner. Since the injection volume in CE is in the nanolitre range, which precludes the use of conventional injection methods, alternative approaches have to be pursued. Hydrodynamic injection and electrokinetic injection have turned out to be the most widely employed sampling techniques.

Hydrodynamic injection introduces a sample based on a pressure difference in the two sides of the capillary. For a laboratory-built instrument, this is realized by simply lifting up the sample vial together with the capillary inlet for a certain period of time (typically a few seconds). The hydrodynamic force will siphon a band of sample solution into the capillary. For commercial instruments, the pressure drop is created by either applying pressure at the inlet side, or imposing a vacuum at the outlet vial. The injection volume can be calculated based on Poiseuille's law:

$$V_{\text{inj}} = \frac{\Delta P \pi r^4 t}{8 \eta L} = \frac{\rho g \pi r^4 \Delta h t}{8 \eta L} \quad [11]$$

where ΔP and Δh are the pressure and height differences, respectively, while r , t , η and L represent capillary inner radius, injection time, solution viscosity and capillary total length, respectively.

Electrokinetic injection is based on the transportation of sample ions by electrophoretic movement and EOF. Normally a lower voltage than that for separation purpose is applied for a certain amount of time to allow analytes to migrate into the capillary. The

injection volumes of individual components can be calculated through the following equation:

$$V_{\text{inj}} = \frac{(\mu_i + \mu_{\text{eo}}) \pi r^2 V t}{L} \quad [12]$$

where μ_i , μ_{eo} are the mobilities of the analyte and EOF, respectively, and V is the injection voltage. For electrokinetic injection the injected amounts of different analytes are dictated by the mobilities of the respective analytes. Thus it is different from hydrodynamic injection, where the sample plug is of entirely the same composition as the original sample solution. To avoid sample injection bias, hydrodynamic injection is preferred. However, in some circumstances hydrodynamic injection may be impracticable (e.g. owing to the high viscosity or low permeability of the separation medium). Electrokinetic injection is then the only viable option, such as in capillary gel electrophoresis. On the other hand, sometimes electrokinetic injection may be exploited in favour of CE operation. For example, it can be employed to diminish the interference of the sample matrix if the components concerned are of low mobilities. Moreover, if the sample is of low conductivity, then sample enrichment during electrokinetic injection is possible by taking advantage of the sample-stacking effect.

Detection

In CE, sample separation is accomplished in an electrolyte solution, so detection strategies analogous to HPLC are adopted. Compared with HPLC, CE column efficiencies are at least one order of magnitude higher, which suggests that solute bands will be narrow and the average concentration of the analyte zone is several times higher than for HPLC. As far as a concentration-sensitive detector concerned, this implies a larger detection signal output. However, so far for CE the concentration sensitivity is usually lower than its HPLC counterparts. This apparent contradiction stems mainly from the small sample size, which poses great difficulties for detection. The fundamental detection schemes in CE fall into three categories: optical (UV absorptive and fluorescent) detection, electrochemical detection, and various hyphenating techniques (typically mass spectrometric detection). The sensitivities of the different detection methods are compared in Figure 7.

UV adsorbance This is the most commonly used detection method for CE, mainly because of its simplicity. It is frequently implemented by modifying a HPLC-type UV detector. The normal flow cell is

Figure 7 Comparison of sensitivities of various CE detection methods. (Adapted with permission from Landers JP (ed.) *Handbook of Capillary Electrophoresis*, 2nd edn, chap. 10, pp. 425–448. Boca Raton, FL: CRC Press.)

removed and the capillary is mounted directly between the incident lens and photocell, in conjunction with a corresponding aperture. Such on-column detection configuration, though easy to execute, provides only a moderate detection sensitivity with the lower detection limits around 10^{-5} to 10^{-6} mol L $^{-1}$, as it is associated with two major problems. First, since the capillary is illuminated radially, the maximum optical path is equivalent to the inner diameter of the capillary. This severely reduces the achievable absorbance according to Lambert–Beer’s law. Second, due to its unique cylindrical geometry, the capillary tends to act like a lens to defocus the incoming light, thus posing difficulties in light orientation and collection. As a consequence, signal noise and nonlinearity are further aggravated. By bending the capillary into Z-shape or creating a bubble feature on the capillary body, the optical pathlength can be considerably increased. These efforts, coupled with improved detection optics, enhance the detection limits to 10^{-7} mol L $^{-1}$. The capillary can also be connected to an HPLC-type flow cell (pathlength ~ 1 mm) as in the HP system.

Fluorescence detection Fluorescence detection is so far the most sensitive detection mode available to CE due to the fact that the measurement is performed against a ‘dark’ background, and fluorescence intensity is less pathlength dependent but directly proportional to excitation power. On-column fluorescent detection can also be realized through adaptation of an HPLC-type detector. Once again, due to the presence of the lens effect of the capillary, improvement of the detection optics is necessary to ensure better

focusing of excitation light and more effective collection of emission light. An important development in CE fluorescence detection is the introduction of laser-based excitation sources. Owing to its outstanding coherence, a powerful laser source can be focused into an extremely sharp beam to illuminate the core part of the capillary, thus producing emission light of high intensity. As a result, detection limits of 10^{-9} – 10^{-11} mol L $^{-1}$ can be obtained routinely, which is at least two orders of magnitude more sensitive than the conventional approach. Single molecule detection has been demonstrated by fine-tuning the CE system and utilizing laser-induced fluorescence (LIF) detection. A major drawback of fluorescence detection is that the number of analytes with native fluorescence is far less than that with UV absorbance. Therefore, to make use of this highly sensitive detection scheme, derivatization of analytes by tagging with a fluorescent group is often needed.

Indirect photometric detection For compounds without any chromophore, indirect detection offers a simple, effective way to take advantage of the convenience of on-column optical detection. Here a UV-absorbing or fluorescent compound with the same sign as the sample ions is added to the running buffer to provide a stable background. During the electrophoretic separation, the sample ions will displace a certain amount of background ions due to electroneutrality requirements. Thus the passage of a sample zone through the detection window will appear as a negative peak. In principle, the quantification of a sample in such a way involves differentiating a signal from two large responses, hence the detection

sensitivity is lower than that for direct photometric detection. To achieve an acceptable detection limit, the background concentration should be kept low. Under such circumstance, any mismatch of mobilities between the sample ions and background co-ions will give rise to a considerable electrodispersion, hence leading to severely distorted peaks. Therefore, selecting a suitable CE background is of special significance for the implementation of indirect optical detection.

Electrochemical detection In electrochemical detection, sample bands are monitored in terms of an electrical signal. Depending on the application, the measured quantity can be conductivity, voltage or current. Accordingly it is referred to as conductimetry, potentiometry or amperometry, respectively. Unlike optical detection in which the measurement output depends strongly upon the available volume, in electrochemical detection the signal relates only to the part of solution that is directly contacting the electrode surfaces. Thus, wherever volume insufficiency precludes the employment of photometric detection, e.g. in case where ultra-narrow bore capillary is used to facilitate fast separation, electrochemical detection may still be a viable choice. Moreover, as long as the analyte is electrochemically active, the detection can be performed directly without involving derivatization, as it may be for photometric detection. Due to these advantages, electrochemical detection gradually gains its popularity in CE practice.

There are two major difficulties involved with implementing electrochemical detection for CE. The first comes from the fact that, it is not easy to make an electrochemical detector function well in the presence of a high voltage, because the separation voltage will produce noise that swamps the minute response of the analytes. Thus, decoupling of the separation electric field from the detection system has to be done to facilitate the measurement. The insulation of the separation voltage can be realized by introducing a fracture or a gap structure in the capillary through which the electrical grounding is made, such that the segment behind the fracture or the gap can be used for the accommodation of the electrochemical electrodes. Alternatively, to shield off the high voltage, the detecting elements may be mounted immediately outside the outlet of the separation capillary. A more elegant way is to etch the capillary end to generate an enlarged conical cuvette from where the detecting electrodes are installed. In this way the interference of high voltage can be eliminated because the electric field decays very rapidly before the enlarged conical part. The second difficulty stems from the need to

fabricate microelectrodes and mount them into an extremely small space, usually defined by the separation capillary. While the current state-of-the-art allows the preparation of microelectrodes with dimensions down to several μm , the installation of the microsensing elements to the detection region is a task requiring complicated microfabrication techniques and great patience. All three types of electrochemical detection have shown their feasibility in CE with typical detection limits in the range of 10^{-7} – 10^{-9} mol L $^{-1}$.

Hyphenation with mass spectrometry Following the great success in interfacing HPLC with mass spectrometry, it is a logical move to explore the potential of CE-MS. For a successful implementation of CE-MS, keeping a proper electrical contact at the MS side is essential. This has been achieved through a variety of means, such as contacting via coaxial sheath flow, or through a liquid junction. Sheathless contact has been realized by attaching the metal-coated separation capillary tip directly to the ion source emitter. For sample ionization and transportation, the electrospray ionization interface (ESI) is predominantly adopted, mainly because ESI is operated under almost atmospheric pressure, thus not conflicting with CE separation. Moreover, ESI ionization works with electrostatically induced nebulization, in which compounds are ionized with different charge status depending on their relative molecular masses and shapes. In principle, this allows determination of relative molecular mass for a large range of compounds, from small molecules to large biopolymers (such as proteins and polysaccharides). Thus it is applicable to all types of CE analytes. As for the mass analyser, the high efficiency of CE separation demands a mass analyser with a fast scan rate. The time-of-flight (TOF) mass spectrometer is probably the most promising candidate, but the quadrupole mass spectrometer is currently the workhorse for CE-MS owing to its commercial availability and relatively low cost. Its insufficient scan speed may be compensated partially through the manipulation of the electric field, i.e. when a certain analyte is migrating out of the capillary, the applied voltage can be reduced temporarily, such that the analyte of interest will remain in the ionization chamber for a longer time. With careful optimization of parameters, CE-MS has shown detection limits in the attomole range (10^{-18} mol mass).

Separation Formats of CE

One of the advantages of CE is that many types of separation can be performed with the instrument

described in Figure 2. This is made possible by simply altering the separation medium inside the capillary and utilizing an appropriate buffer system. The commonly employed separation formats in CE can be divided into the following.

Capillary Zone Electrophoresis (CZE)

Among the various CE formats CZE is the simplest and most popular. Here a homogenous free solution is employed to maintain a constant electric field along the capillary. Ionic species are separated inside this supporting solution according to their different charge-mass ratios, thus forming segregate zones. The desired separation selectivity can be achieved by simply optimizing the parameters of the carrier electrolyte particularly pH, as well as ionic strength and the type and concentration of various EOF modifiers. A number of secondary equilibria are available to strengthen the separation selectivity further.

Although CZE is commonly performed with an aqueous buffer, it can also be implemented in a non-aqueous medium by using organic solvents and compatible conductive salts. The effect of replacing water with an organic solvent in CE can be understood from the fact that organic solvents possess significantly different viscosities and dielectric constants compared with water. Thus, changes in the magnitude of EOF and migration behaviours of charged analytes are expected in non-aqueous CE, which can be seen from eqns [2] and [4]. Furthermore, organic solvents differ in their capacity to stabilize equilibria. Thus, in organic media, the charge status of organic analytes can be dramatically different from that in an aqueous medium, hence leading to quite different separation selectivity. Additionally, it is evidenced that organic media are capable of promoting certain mechanisms such as inclusion interaction and ion-pair formation, which enhance possibilities of achieving the desired separation. Moreover, with a water dominated buffer, it is very difficult to conduct CE separations of hydrophobic analytes. Under such circumstances, switching to a non-aqueous buffer system would provide an efficient solution. Finally, it is noted that, when an organic medium is utilized for CZE separations, the electrophoretic current is reduced considerably. As a result, even though capillaries of relatively wide inner diameter are employed, Joule heating is at a manageable level, thus enabling the enhancement of detection sensitivity through the usage of wide bore capillaries. In short, non-aqueous CZE is an attractive means for extending the applicability of CE.

Capillary Gel Electrophoresis (CGE)

For this format, polymeric networks are present along the electrophoretic pathway of analytes, which causes charged species to be resolved on the basis of their physical sizes rather than charge-to-mass ratios. Accordingly this separation process is also commonly known as 'molecular sieving'. It is particularly suitable for the separation of biomacromolecules consisting of numerous repeat charge units, such as DNA fragments, SDS-denatured proteins and polysaccharides (Figure 8). CGE may be considered as an adaptation of traditional gel electrophoresis into its capillary format. However, traditional gel electrophoresis use only cross-linked polyacrylamide (so called 'chemical gel'), while for CGE both cross-linked polymer gels and various polymer solutions can be employed to create the sieving pores. The use of polymer solutions instead of chemical gels facilitates renewing of the sieving medium by simply flushing out the original solution, and refilling with another. It also alleviates some technical problems associated with chemical gel such as gel shrinkage, bubble formation and matrix collapse, hence improving the separation reproducibility.

(Adapted with permission from Yin HF, Lux JA and Schomburg G (1990) Production of polyacrylamide gel filled capillaries for capillary gel electrophoresis (CGE): influence of capillary surface pretreatment on performance and stability. *Journal of High Resolution Chromatography* 15: 624–627.)

Capillary Isotachopheresis (CITP)

In CITP, a leading electrolyte of higher mobility than any of the sample components is filled into the separation capillary and outlet reservoir, while a terminating electrolyte of lower mobility than any of the sample components is placed in the inlet reservoir. The sample is applied from the capillary inlet. This arrangement ensures that there will be no mixing of sample with the two electrolytes during the whole electrophoretic process. As a consequence, upon application of an electric field, the main change happens inside the sample band itself, i.e. the sample components tend to 'queue up' according to their effective mobility orders. These components are relocated with corresponding changes in their concentrations and band lengths. Ultimately a series of consecutive 'pure zones' containing only the individual substances are formed. This is the steady state as there will be no more changes for the sample except that all the zones will continue to migrate out of the capillary with an identical velocity (hence the term 'isotachopheresis'). Unlike the other types of CE separation, in CITP the concentration of a specific zone is predetermined by the concentration of the leading electrolyte and the relative mobility of the ion of interest with respect to the leading electrolyte, while the sample amount is reflected by the zone length. Due to the unique stepwise increase in electric field starting from the leading electrolyte side, which prevents a component from drifting off its own band, sharp boundaries can be maintained more readily. Therefore CITP can be implemented using tubes of relatively large i.d. (e.g. 0.2–0.8 mm). Nevertheless, CITP as an analytical tool has largely lost its popularity since the advent of CZE, probably due to the fact that a thorough knowledge of the sample is required before the separation. Furthermore, the isotachopherogram is usually step-shaped, and the steps are not time related, thus rendering automatic identification and quantification difficult. CITP is often applied as a sample pre-concentration step before CZE separations to enhance detection sensitivity.

Capillary Isoelectric Focusing (CIEF)

This is another example of an adaptation of a conventional electrophoresis principle to a capillary format. CIEF exploits differences in isoelectric points (pI s), a unique characteristic of amphoteric compounds under which its acidic and basic groups dissociate to an equal extent, so that the whole molecule exhibits no net charge. It is only suitable for the separation of compounds like amino acids, peptides and proteins. The operation of CIEF relies on a mixture of carrier

ampholytes with isoelectric points in a certain range and in close proximity to each other. Such a mixture is commonly formed by a series of synthetic poly-amino polycarboxylic acids. The capillary is filled with the carrier ampholyte solution and a small amount of sample, and dipped into the buffer reservoirs that contain acid and base, respectively. Under the electric field, different ampholytes will migrate along the capillary until they reach positions corresponding to their pI values, where they stand still. Collectively a stable pH gradient is formed across the capillary. The sample components, too, will migrate until they find positions equivalent to their pI values. When such a steady state is obtained, an immobilization step (by utilizing electrophoretic movement or pressure) is performed, and the separated analyte bands will be forced out and passed through the detector. If the carrier ampholyte mixture is well prepared and a sufficient time is allowed for the electric focusing process, a very high column efficiency can be realized.

Micellar Electrokinetic Chromatography (MEKC)

Neutral species can never be resolved with traditional electrophoretic techniques since they have no electrophoretic mobility. After the birth of CE, this problem was solved by Terabe *et al.* through the addition of a charged surfactant to the running buffer. Typically a negatively charged surfactant is added at a concentration above its critical micelle concentration (CMC). Under such circumstances, micelles are formed, which allow neutral compounds to be retained based on their hydrophobicities. Under an electrical field, the negatively charged micelles move toward the anode side, while a strong EOF moves toward the cathode side (Figure 9). As EOF usually exceeds the electrophoretic mobility of micelles, the micelles will eventually be swept out in the same

Figure 9 Separation mechanism of MEKC.

Figure 10 Separation of small neutral aromatic compounds by bile salt-based MEKC. (Unpublished results.)

direction. Thus a migration time window is defined within which the neutral compounds can be separated according to their affinities for the micelle micro-environment. If a positively charged surfactant is used, then similar resolution of neutral analytes can again be obtained, the only difference being that the EOF will be reversed owing to the adsorption of cationic surfactant molecules onto the capillary. The polarity of the separation voltage, therefore, needs to be reversed. The micelle-forming reagents for MEKC are not limited to synthetic detergents – any chemical with similar surface activity can be employed. These include biogenic surfactants such as bile salts (**Figure 10**), and as some synthetic high mass-to-charge polymers.

Affinity Capillary Electrophoresis (ACE)

Compared with other types of CE techniques, ACE represents a relatively recent development. Introduced in the early 1990s, ACE is performed on the basis of specific or non-specific affinity interactions between receptor and ligand molecules, typically biomolecules. Theoretically, if either receptor or ligand is a charge species, their binding complex would show a different electrophoretic mobility from that of the parent molecule due to the changes in charge-mass ratio. Thus, measuring the changes in electrophoretic mobility of the receptor via CZE mode provides an excellent way to study aspects of the receptor–ligand binding.

Depending on the binding strength of the receptor–ligand pair and the operational procedure, ACE

can be divided into three different categories, namely, non-equilibrium mode, dynamic equilibrium mode and immobilizing mode. Equilibrium ACE is well suited to studying strong binding systems, in which the sample is injected as an equilibrated mixture of receptor and ligand, whereas the electrophoresis medium contains only the supporting buffer. In such cases, CE serves merely as a tool to separate and determine the free and bound receptor molecules. Dynamic equilibrium ACE is typically employed for weak to moderate binding system, in which the receptor is injected as the sample, while ligand of varied concentration is incorporated in the running buffer. In this case, free and bound molecules are not separated due to the fast on-and-off kinetics, but rather, they are detected as single peaks. The immobilizing mode is self-explanatory, for which ligand is attached to the capillary wall, or more commonly, onto a supporting material via an appropriate bonding chemistry, while sample (receptor) is driven over the active surface by application of an electric field. Again, the migration behaviour of the receptor is a good indication of receptor–ligand interaction strength.

ACE has become a powerful tool in diverse fields, including the measurement of binding constants, the study of binding kinetics, the determination of interaction stoichiometry, the characterization of biomolecules and the separation of enantiomers, etc. ACE has been applied to the investigation of a number of biologically important systems, such as the interaction of polypeptides with immunoglobulins, polypeptides, carbohydrates, nucleic acids, drugs, etc.

ACE bears some resemblance to classical gel affinity electrophoresis and conventional affinity chromatography, in that they all utilize specific interactions to effect separations. However, ACE inherently has an unsurpassed advantages, that is, the buffer conditions (ionic strength and pH) can be finely tuned to give a perfect mimic of the real physiological environment, so that more precise characterisation of many binding processes is possible, provided the wall adsorption problem can be addressed properly.

Applications

The introduction of CE has resulted in a dramatic expansion of the applicability of electrophoresis as a separation tool. While conventional slab gel electrophoresis is mainly limited to the separation of biosubstances such as proteins and DNA fragments, CE has been utilized to resolve a much broader spectrum of substances, ranging from simple ions

through small molecules to macromolecules. High mass biomolecules such as proteins, DNA and polysaccharides can be separated by CZE as well as CGE. Smaller charged molecules such as amino acids, peptides, organic acids and amines can be resolved via CZE. Simple ions, both cations and anions, can be easily separated via CZE with conductivity detection. CZE separations of ions with indirect UV detection, dubbed as capillary ion analysis (CIA) has been accepted rapidly as an alternative to ion chromatography owing to its simplicity, speed and low cost. The separation of various neutral compounds has been made possible through MEKC or CEC. Chiral separations, an area hardly touched by conventional electrophoresis, is increasingly carried out by CE. Many chiral selectors (cyclodextrin derivatives, amino acids, proteins, optical micelles, etc.) may be added to the buffer solution to induce enantiodiscrimination based on one of several mechanisms (host-guest complexation, ligand exchange and solubilization by micelles, etc.). The unequal stability of dynamically formed diastereoisomers cause the optical isomers to be moved out of the capillary with different velocities, and enantioseparation is achieved. Because of its far-reaching capabilities, CE is becoming ubiquitous in almost all analytical fields.

Future Prospects

The introduction of CE in the early 1980s has had a huge impact on numerous scientific fields. It can be anticipated that in the future CE will continue to evolve into a fully fledged analytical technique that will benefit many research disciplines. Based on the characteristics of CE and its current status, several directions deserving special attention can be envisaged.

CE is hailed for its high column efficiency and outstanding mass sensitivity. The concentration sensitivity of CE remains relatively low compared to HPLC, thus limiting its applications in areas such as trace impurity determination and environmental analysis. Therefore, improving the detection sensitivity will continue to be a topic for development. Creative detection configurations, interplay from micro-mechanic and microelectronics, together with advancement of light sources, may remarkably enhance the sensitivity of optical detection. To facilitate the use of electrochemical detection, efforts must be made to provide better microelectrodes with reasonable ruggedness. With the enhanced performance and reduced cost, a more common use of sophisticated hyphenation techniques such as CE-MS is expected.

On the other hand, the ability of CE to handle extremely small sample quantities is attractive for the direct probing of micro-entities. The recently emerged single cell analysis is a good example of this. With further improvements in sampling techniques and detection schemes, it is believed that in the near future, CE-based methodologies will allow us to investigate the chemistries of a wider spectrum of cells, thus enriching our knowledge about many biological processes essential to life.

Finally, due to its instrumental simplicity, CE is amenable to further miniaturization. CE on a glass chip has been successfully demonstrated by borrowing microfabrication concepts from the microelectronics industry. These devices feature the integration of injection, separation and detection, as well as sophisticated designs with intricate patterns and multi-channel arrays, thus producing an unprecedented analytical platform which is fully manipulated by applying voltages. As the plate format possesses an excellent ability for heat dissipation, electric fields up to 2000 V cm^{-1} may be applied across the separation channels, hence shortening the analytical time scale to minutes or even seconds. With continuous maturity of relevant technologies, such an ultra-high speed separation method may provide a solution to some formidable tasks including DNA sequencing.

Introduction

Capillary zone electrophoresis (CZE) is widely recognized as a powerful analytical technique in its own right, known for its high separation efficiency, short analysis times and low-volume sample requirements. These characteristics made CZE a popular method for the analysis of peptide mixtures, protein digests, drug substances and biotechnological products. The coupling of CZE with electrospray ionization mass spectrometry (ESI–MS), first reported by Olivares *et al.* in 1987, has added further capabilities, in particular for obtaining molecular mass information and structural details when tandem mass spectrometry (MS–MS) is used. However, it can be said that the major advantage of such coupling is that the migration time is not the only parameter used for identifying the eluted components. These times are subjected to variations between runs, yet such variations become irrelevant when, in the same run, highly diagnostic mass spectra are obtained.

Depending on the ionization method, CZE can be coupled to a mass spectrometer either directly (online) or indirectly (offline). In the latter mode of operation, ^{252}Cf plasma desorption and matrix assisted laser desorption can be used. The online coupling of CZE is more common and usually performed by electrospray ionization (ESI) or fast atom (ion) bombardment (FAB). Although online CZE/MS is the more common form of application, offline analysis has the advantage of allowing separation in non-volatile buffers, which are highly undesired in ESI.

It goes without saying that every analytical technique has its limitations and CZE/MS is no exception. One of the main limitations of this experimental arrangement is its relatively poor sample concentration/ion sensitivity. Approaches to reduce such limitations included online preconcentration, sample

stacking, and the increasing use of time-of-flight (TOF) analysers which use ESI and TOF analysers with and without a quadrupole in between. The innovative feature of this class of instruments is their fast scanning, which allows the acquisition of a number of full spectra per second. Additionally, as all ions in each spectrum are sampled at the same moment in time, spectra are free of mass discrimination or peak skew typical of slow scanning systems that must scan over a narrow chromatographic/electrophoretic peaks.

Capillary electrochromatography (CEC) is another technique which is currently undergoing a rapid phase of advancement and development. This technique was revived by Jorgenson and Lukacs in 1981; these authors used 0.005 mol L^{-1} phosphate buffer, $170 \mu\text{m}$ packed column and 30 kV separation voltage to separate 9-methylanthracene and perylene. This technique has recently become more diffuse because of a number of advances in both CE instruments and detection techniques including electrospray mass spectrometry. However, on-column UV detection and in-column laser-induced fluorescence detection remain the most commonly used methods. Despite its high sensitivity, the latter method is subjected to interferences by buffer fluorescence. In MS detection, the column is commonly packed right up to the point where the sample is injected into the mass spectrometer. The combination of CEC with mass spectrometry provides reliable molecular weights and in many cases structural information, which makes it highly attractive for a wide range of applications. For more details on this topic, the reader is referred to recent extensive reviews, covering the methodology of CEC and its coupling to MS, by Colòn *et al.* (1997) and Rentel *et al.* (1999). Interestingly, packed-CEC offers the possibility of higher sample capacity and the utilization of simpler mobile phases, which are more compatible with MS.

Experimental Aspects

One of the main advantages of CZE is that it requires simple instrumentation, which generally consists of

a high-voltage power supply, two buffer reservoirs, a capillary and a detector. Coupling of such instrumentation to a mass spectrometer requires the replacement of one of the buffer reservoirs with a suitable interface and some simple electronic circuit to accommodate the presence of an additional 3–5 kV required for the operation of the ion source.

Interfacing CZE to a mass spectrometer has been effected in a number of ways, yet all of them can be traced to two general configurations: liquid junction interface and coaxial sheath flow. The liquid junction interface, first described by Minard *et al.* in 1988, was used to couple a CZE to a continuous-flow FAB source. In such a configuration the CE capillary terminates in a 20 μm block that contains either the matrix solution for FAB ionization or the sheath solution for ES ionization. The inlet of the transfer capillary is aligned in close proximity to the cathode end of the CE capillary, an alignment considered critical, since the gap must be sufficiently wide to allow enough matrix or sheath fluid to maintain a stable ion beam. On the other hand, the same gap should be small enough to prevent analyte diffusion, upon exiting the CE capillary, which would otherwise result in peak broadening. The main disadvantage of this configuration is associated with the dead volume caused by a long transfer line which together with the mixing effects in the interface and the presence of the FAB matrix renders the separation efficiency of this interface poorer than that of the coaxial sheath flow. Liquid-junction interface has been redesigned to allow easier mounting and alignment of the CE and continuous-flow FAB capillaries. The same interface was further modified by Caprioli *et al.* in 1989, who

used it for the analysis of synthetic mixtures of peptides and protein digests.

The first successful coupling of CE with MS was effected by Olivares *et al.* in 1887, wherein the cathode end of the CE capillary terminated within a stainless-steel capillary which completed the electrical circuit and established contact with the CE side. An improved version of this interface was developed by the same research group, where the metal contact at the CE terminus was replaced by a thin sheath of liquid flow. In comparison with the liquid-junction interface, the coaxial sheath-flow interface provided both better sensitivity and better resolution, yet this did not mean that the interface was trouble free. A number of difficulties can derive from the use of sheath liquid: ionic and neutral species within this liquid compete for protonation in the ESI process, thus lowering the overall sensitivity. The composition of the sheath liquid commonly includes a volatile organic acid (1% formic or acetic acid) in a mixed water–organic solvent, a composition which is different from that of the electrophoretic buffer. During the CE, sample ions and other species present in the buffer exit the capillary at the MS end, and, simultaneously, counterions from the liquid sheath enter the column and migrate toward the injection end. These moving ion boundaries can influence migration order, times and resolution. The same phenomenon has the advantage of allowing some analysis in the presence of difficult-to-spray electrolytes (such as phosphate- or borate-containing buffers).

Figure 1 gives the up-to-date version of a commercial coaxial sheath-flow interface constructed and marketed by Micromass (Manchester, UK).

Representative Examples

CZE/MS in Peptide Analysis

One of the advantages of coupling CZE to ES mass spectrometry is the formation of multiply charged ions which allows simple analysers such as quadrupoles to measure the mass to charge ratios (m/z) of relatively large biomolecules. Indeed, the majority of CZE/MS applications have been in the field of biological and biochemical research. A number of reports have appeared on the characterization of synthetic mixtures of peptides and proteins, where the unusually high resolution of CZE permits the separation of sequences which may differ by a single amino acid residue. This advantage has been exploited in the use of CZE/ES–MS to examine a number of reaction mixtures of peptides obtained by solid-phase synthesis; two representative examples are considered here. A reaction mixture obtained by solid-phase synthesis of neuropeptide Y (NPY) analogue, [Leu³¹, Pro³⁴]-NPY. This peptide has 36 amino acid residues, a relative molecular mass of 4222 and is known to play a major role in the central and peripheral nervous system. Online CZE/ES–MS analysis of this mixture resulted in a fairly complex UV and total ion current (TIC) electropherograms which, in addition to the target peptide, contained a number of side products. The use of mass spectrometry allowed reliable identification of all the components of the mixture, although some of the side products differed by a single amino acid residue in sequences containing over 30 residues. These measurements allowed unambiguous identification of the various components of the mixture which are summarized in **Table 1**.

A second and less complex reaction mixture associated with the same synthesis was also examined by the same technique which yielded the total ion current electropherogram in **Figure 2(A)**. Deconvolution of the mass spectra in **Figure 2** (panels 1–4) yielded the relative molecular masses 4222 (1), 2441

(2), 3577 (3) and 3789 (4). The first molecular mass coincides with the desired peptide, while the other three masses are associated with a number of incomplete sequences which are summarized in **Table 2** which clearly shows an excellent agreement between the calculated and measured masses, fully based on CZE/MS measurements. Given the complex procedure associated with solid-phase synthesis of peptides, it is evident that the use of online CZE/MS is an indispensable analytical tool for the initial characterization of the product and for providing a reasonable indication on the yield of synthesis.

CZE/MS can also give reliable information on unexpected processes in the course of solid-phase synthesis of peptides. To underline this statement, two cases are considered. A series of newly synthesized peptides investigated, corresponding to portions of the extracellular domain of human granulocyte-macrophage colony-stimulating factor receptor α -subunit. A solution containing 3 mg mL⁻¹ of the peptide [PRAKHSVKIRAADVRLN], $M_r = 2084$, was examined by full-scan CZE/MS, which yielded UV and TIC electropherograms, each of which contained three peaks of almost equal relative heights. The associated ES mass spectra revealed the presence of the desired peptide together with its acetylated version in one of the three TIC peaks. It is fair to say that without the use of online MS detection, the identification of the latter component would have been very unlikely. A second case refers to online CZE/MS of an NPY analogue which exhibited a TIC electropherogram containing seven peaks, two of which yielded $M_r = 4222$ which implied the presence of two different configurations of the same sequence within the same crude of synthesis. This deduction was found in accord with existing literature describing undesirable side products observed in solid-phase synthesis of peptides and small proteins. One such side product can be invoked by the formation of succinimide of the Asp residue (β -aspartyl peptide) which, in the present case, has the same M_r as the

NPY analogue. The mechanism responsible for such reaction is depicted in Figure 3.

Forensic Application of CZE/MS

Most drugs of forensic interest are commonly analysed by GC/MS or extraction followed by IR analysis. Separation of benzodiazepines and ergot alkaloids by GC is difficult and differences in the IR

spectra are small. On the other hand, the analysis of these compounds by CE/MS is characterized by short analysis times and specific MS information. Forensic drug chemists, investigating drugs of abuse, also find the analysis of drugs such as LSD challenging because of microgram quantity dosage and the fact that GC/MS analysis is rather demanding owing to column adsorption and thermal lability. This is also true for psilocybin, the psychoactive agent in certain

mushrooms, owing to the presence of the highly labile phosphate moiety. The absence of complex preparative extractions for CE analysis of both drugs allows their separation without causing undesired decomposition.

The fact that many forensic drugs have closely related isomeric structures renders CE/MS a powerful tool for their separation and identification. For instance, phenethylamines are historically a difficult group to analyse due to the large number of isomers including both D- and L-optical isomers. Twelve optical isomers of ephedrine, pseudoephedrine, norephedrine, norpseudoephedrine, amphetamine and methamphetamine have been separated in under 30 min using CE. It is worth noting that this class of compounds tends to give strong $[M + H]^+$ signals in ES ionization which makes them ideal for CZE/MS analysis.

A separation of 18 common drugs of abuse was accomplished in less than 40 min using CE buffered with phosphate/borate, with sodium dodecyl sulfate (SDS) as a micellar phase and acetonitrile as an organic modifier. The main advantage of this method over other screening techniques is that acidic, basic and neutral drugs can be screened through a single analytical method, where extraction procedures are unnecessary.

Clandestine manufacturers of illegal drugs pose additional challenges to the forensic scientist, since samples submitted for analysis tend to contain complex mixtures of chemicals, including thermally reactive and labile components. CZE with and without MS detection can be a powerful tool for such type of analysis. For example, the frequently encountered methamphetamine can be analysed by CE allowing the identification of its isomeric composition which can be eventually used to construct evidence concerning its synthetic pathway and the source of the sample.

An additional problem with samples from clandestine laboratories is the presence of unreacted precursors and adulterants that may interfere with the analysis of the target compound(s). For instance, under typical GC/MS conditions, certain mixtures of chemicals associated with methamphetamine will derivatize the illegal drug to a compound that is not controlled, resulting in an inconclusive analysis. Using a number of CE methods, such interference can be easily avoided.

CZE/MS is also highly suitable for the analysis of biological samples which may contain traces of illegal drugs or poisons in a complex matrix. Extensive reviews cite over sixty references on the use of CE for the analysis of drugs in biological samples including drugs of abuse in urine, cocaine and morphine in hair

and barbiturates in serum. Other examples include the chiral separation of racemethorphan and racemorphan in urine using a cyclodextrin/SDS/propanol buffer and the micellar CE separation of nitrazepam and its metabolites in urine. An extensive review is available on the use of CZE coupled to tandem mass spectrometry to identify a variety of drugs and metabolites. All these reviews are listed in the **Further Reading**.

Forensic Analysis of Inorganic Explosives

Capillary electrophoresis is also widely used in the analysis of inorganic ions in criminal cases, material such as black powder, flash powder, ammonium nitrate and home-made explosive mixtures. The inorganic anions resulting from an explosive reaction of such materials are among the most important evidence used to determine the nature of an inorganic explosive. For many years, the most powerful tool in these investigations was ion chromatography (IC). The introduction of CE for anion analysis provided a simpler, faster and slightly more sensitive technique for performing such analysis. It is interesting to note that CE separations are based on differences in charge-to-mass ratios of the solvated ions, while IC separations are the result of complex interactions between the ions and the stationary phase. As a result, the migration order is quite different in the two methods and a nearly orthogonal relationship exists between the relative retention times.

The reliable analysis of certain alkyl-substituted organophosphorus acids, which are the primary hydrolysis products of neurotoxic agents, has become very important in the last few years owing to the likelihood of an international agreement that will forbid the development, production and stockpiling of chemical warfare agents and weapons. CZE coupled to ion spray mass spectrometry was applied in the negative ion mode to investigate five organophosphonic acids, which are the primary hydrolysis products of neurotoxic agents. The MS spectra exhibited a very abundant $[M - H]^-$ signal with minimal fragmentation. The authors reported sensitivity in the range 10–30 pg using the single-ion recording (SIR) mode.

Conclusions

The examples cited in this work have to be considered as only a part of the capabilities of CE with and without MS coupling. The literature cites varied areas of application of such powerful methodology. As new applications of CE continue to appear, the

advantages and importance of CE in conjunction with mass spectrometry have also become appreciated. Analytical chemists are faced with the challenge of increasing sample complexity and decreasing sample quantities. Because of the complexity observed with most biological mixtures, there continues to be a need for the development of a highly efficient separation technique in conjunction with a sensitive and specific detector. The low quantities of analytes often available require nanoseparation techniques. The mass spectrometer is a selective and broadly applicable detector for analytical separations. It can provide information regarding the structure of unknown components present in a sample mixture with high specificity and sensitivity. The coupling of CE with MS combines the extremely high-resolving power and structural information in one system. Like any other separation technique such as GC–MS and LC–MS, the principal advantage of CE–MS is that analytes are identified by both their differential separation and their molecular masses and/or fragmentation patterns. An analytical separation that precedes MS analysis is often necessary to assure correct interpretation of the mass spectral data.

Fast, high-efficiency separation techniques are becoming ever more important in the race to discover new drugs. The potential complexity of libraries produced by automated parallel synthesis, combinatorial and genetically manipulated natural product chemistries are driving many developments in separation sciences.

CE, CEC and nano-LC are all potential candidates for such analyses and each has a requirement for a fast, sensitive detection system.

Capillary Electrophoresis–Nuclear Magnetic Resonance

K. Pusecker and J. Schewitz, University of Tübingen, Tübingen, Germany

Copyright © 2000 Academic Press

Miniaturization is an important current trend in separation science and the development of capillary elec-

trophoresis (CE), capillary HPLC (cHPLC) and capillary electrochromatography (CEC) are milestones in this respect. The electrophoretic techniques especially can achieve rapid and efficient separations using only very small volumes and they have become research tools with widespread applications. The advantages of this miniaturization are obvious: less sample is

required, less solvent is consumed, and the separation times are shorter.

The second trend in separation science is toward information-rich detection modes. Although UV-VIS fluorescence, and electrochemical detectors provide sensitive and simple detection, the information is generally not sufficient for unequivocal characterization or structural elucidation of compounds. For this purpose the coupling of capillary separation methods with electrospray mass spectrometry (ESI-MS) has proven to be highly successful. ESI-MS is an extremely sensitive detector and in many cases information about mass and fragmentation gives detailed structural information.

The enormous sensitivity gain in nuclear magnetic resonance (NMR) spectroscopy in recent years also enables the wider application of directly-coupled HPLC–NMR. NMR spectroscopy is considered one of the most powerful methods for determining chemical, dynamic, and spatial structural properties of organic compounds. Its capability to distinguish between most structural, conformational, and, in special cases, optical isomers is highly complementary to the information gained from MS experiments. NMR spectroscopy is nondestructive and spectra are recorded in solution. A combination with additional detectors is possible, e.g. HPLC–UV–NMR, HPLC–MS–NMR.

The miniaturization of liquid chromatography (LC)–NMR has additional advantages. The small volumes of eluent consumed in capillary separation techniques make the use of fully deuterated solvents economically feasible. Therefore, problems associated with protonated solvents are prevented. NMR solvent suppression techniques which can lead to distortion of parts of the spectra are no longer necessary. Thus, the entire range of the ^1H -NMR scale can be used in one- and two-dimensional experiments. The supplementary benefit of conserving material is particularly interesting for valuable samples, such as natural products or labelled proteins.

However, the NMR spectrometer is one of the least sensitive of all possible LC detectors. The miniaturization of the LC–NMR coupling for the application of capillary separation techniques requires a reduction of the detection volume by a factor of approximately 1000 in comparison to conventional LC–NMR systems. On these conditions, the techniques seemed to be incompatible. Despite these problems, because of the great potential of the technique, efforts have been made in the past few years to enable coupling of capillary techniques to NMR spectroscopy. To date, two different experimental approaches have been developed and evaluated. They differ mainly in the type of radiofrequency (rf) coil that is used for the

NMR detection. This variation leads to different strengths and weaknesses of the two systems, which allow or hinder their use for particular applications.

Set-up for CE–NMR Coupling

The design of an interface for the coupling of capillary separation techniques with NMR spectroscopy is simple in principle. Since phase transfer is not necessary, detection can be carried out in the fused-silica capillary, which is used for CE separation. The detection takes place on-column similar to a common UV detection. The capillary is built into an NMR probe head. Even the inlet and outlet vials of the CE can be incorporated inside this probe, but for practical reasons to allow easy sample loading, it is more useful to retain the inlet outside the NMR spectrometer. In any case both vials are maintained at the same height to avoid siphon flow. The separation equipment, e.g. power supply or HPLC pump, have to be placed outside the magnetic field. High voltage is applied to one end of the capillary and the other vial is grounded. With vials outside the magnet (inlet vial or both vials) a capillary length of approximately 150–200 cm is required. This means the capillary is three to four times longer than a common CE capillary.

The limiting factor of the whole system is the low sensitivity of the NMR spectroscopy. The parameters that affect the detection limit are the type and size of the radiofrequency coil, the detection volume, and the so-called filling factor, the ratio of coil and sample volume. A optimal detection cell fills the purpose-built microcoil completely. Furthermore, the inner diameter of the used fused-silica capillaries have to fulfill the chromatographic requirements. Especially for electrophoretic techniques, the inner diameter of the capillaries is therefore limited ($\leq 100\ \mu\text{m}$) and the size of the coil has to be adapted to these requirements.

Two different microcoil NMR configurations have been used for online coupling of capillary separation techniques with NMR spectroscopy. One approach is based on a solenoid rf coil wound directly on the CE capillary (Figure 1). The detection volume for the system is thereby determined by the inner diameter of the capillary and the length of the coil. With $75\ \mu\text{m}$ capillaries and a typical coil length of approximately 1 mm, detection volumes of 5–8 nL are obtained. Solenoid coils are positioned in a horizontal direction in the NMR spectrometer, perpendicular to the main magnetic field. The other approach uses saddle-type rf coils (Figure 2). The detection unit consists of a coil fixed onto a glass tube, into which the capillary is inserted. Due to technical problems, the reduction of

Figure 1 (A) Solenoid NMR interface. (B) Instrumentation of the solenoid NMR probe system. Adapted with permission from Gfrörer *et al.* (1999) *Analytical Chemistry News and Features* 71: 315A–321A, and Olsen *et al.* (1999) *Analytical Chemistry*, 71: 3070–3076.

the coil diameter is restricted. The smallest available coils have diameters of 1.5–2.0 mm and a length of 5–9 mm. To optimize the filling factor, special NMR capillary cells have been fabricated to a predetermined size by etching a standard fused-silica capillary with a HF solution only in the detection region. While the inner diameter in this part was widened, the rest

of the capillary remained nearly the original diameter of 75 μm allowing the application of electrophoretic separation techniques. By varying the duration of etching, detection volumes between 180 and 440 nL were obtained. In contrast to the solenoid coil, the saddle coil is situated vertically in the NMR spectrometer, parallel to the main magnetic field.

Development of the Solenoid NMR Probe System

In 1994 Wu *et al.* described the first capillary electrophoresis NMR system with a solenoid rf microcoil. The coils were produced by winding copper wire around fused-silica capillaries with inner diameters of 75–530 μm . The resulting NMR detection cells had volumes of 5–200 nL. The possibility of an online NMR detection was shown for CE separation of amino acids. The set-up was not suitable for routine operation, e.g. each sample had to be loaded externally, after which the probe was inserted. The structural information of the NMR spectra was limited due to large line widths (7–200 Hz). The electrophoretic current had a clear effect to the NMR line width.

Further developments of this solenoid system focused on the NMR detection of mass limited samples. In 1995, Olson *et al.* presented a new microcoil design. Several modifications were devised to obtain higher resolution. The fabrication of the coil was slightly changed and the outer diameter of the capillary was increased (357 μm o.d., 75 μm i.d.). The main improvement was the reduction of the effect of magnetic susceptibility caused by the proximity of the rf coil to the sample. A perfluorinated organic liquid was used to match the susceptibility of the surrounding medium to that of the coil material. This lowered the static magnetic field inhomogeneities in the sample and thus improved resolution and line shape (line width < 1 Hz). As a consequence of the improved resolution, the sensitivity of the system increased. Limits of detection in the range of 100 pmol were reported for arginine, sucrose and a seven amino acid peptide using a 5-nL detection cell.

In 1998 Subramanian *et al.* presented solenoid microcoil probes for direct or inverse ^{13}C -NMR detection. Heteronuclear NMR techniques are an important component in determining full-structure information on unknown compounds. Due to the low relative sensitivity of ^{13}C -NMR, the detection volume was increased in comparison to the previous design. Capillaries with inner diameters of 700 μL were used for the fabrication of the probe. The resulting detection cells had volumes of 550–1200 μL . The natural-abundance ^{13}C -NMR limit of detection was below 100 nmol. One-dimensional ^{13}C -NMR spectra and two-dimensional ^1H - ^{13}C inverse-correlation NMR spectra were acquired using samples in the tens of micrograms range.

In 1999, Olson *et al.* applied the optimized NMR interface for CE–NMR coupling. Arginine, glycine and triethanolamine were used as model compounds

to investigate in more detail the influence of the electrical current on the NMR signals. It was confirmed that for geometries, in which capillary and static field are not parallel, the electrophoretic current induces a magnetic field, which degrades the spectroscopic information obtainable from the CE–NMR spectra. To circumvent this effect, the electrophoretic voltage was periodically interrupted to obtain high resolution spectra. In addition, different sample-loading techniques including field-amplified stacking for sample preconcentration, were evaluated. Flow profiles were observed by the detection of the water signal of the loaded samples.

Development of the Saddle-type NMR Probe System

First results of this approach were reported by Behnke *et al.* in 1996. The LC capillary was mounted inside a modified NMR microprobe equipped with a 2.5-mm double-saddle Helmholtz coil. In static NMR experiments, a line width of 3 Hz could be achieved in 75- μm i.d. capillaries. However, this arrangement adversely affected the filling factor of the system and thus the sensitivity using this configuration was reduced significantly. First, coupling experiments with this system were performed with cHPLC. In comparison with CE, cHPLC provides a higher sample capacity and offers the possibility of peak preconcentration by the application of gradient elution. Online and stopped-flow NMR experiments of dansyl amino acids were carried out in 315- μm i.d. capillaries.

The sensitivity of the saddle-type system was improved by Schlotterbeck *et al.* in 1997. Decreasing the inner diameter of the rf coil from 2.5 to 2 mm improved the filling factor and thus the sensitivity and the line shape of the system. For online cHPLC–NMR experiments, the inner diameter of the capillary was increased to 180- μm i.d. in the detection region and this led to a limit of detection of 150 pmol. The feasibility of the interface was proved by its application to vitamin derivatives. The structure of a so-far unknown kitol, a retinyl acetate dimer, was determined from one- and two-dimensional ^1H -NMR spectra in both continuous and stopped-flow measurements.

In 1998 the configuration was modified for the application of electrophoretic techniques by Pusecker *et al.* The most important alteration was a purpose-built CE–NMR capillary. This capillary had a detection cell with an inner diameter of 190 μm corresponding to a detection volume of 240 nL, whilst the rest of the capillary still had the usual CE diameter of approximately 75 μm . CE–NMR measurements proved that for the saddle geometry, in which capillary and static magnetic field are parallel, the

spectroscopic information is not degraded by a magnetic field gradient induced by the electrophoretic current. The suitability of the configuration for electrophoretic methods was investigated by the application of CE and CEC–NMR spectroscopy to model systems. The favourable capabilities of the CEC–NMR coupling in view of the increased sample capacity and separation efficiency were demonstrated for the separation of five alkyl benzoates.

The optimization of the filling factor by a further increase of the detection volume to 440 nL improved sensitivity and line shape. A line width < 0.8 Hz was reported by Schewitz *et al.* The system was applied to the analysis of mixtures of pharmaceuticals and drug metabolites, nucleotides, peptides, natural products and ingredients of soft beverages. The possibility of CE stopped-flow NMR experiments was shown for an adenosine dinucleotide. The flow was halted by switching off the voltage at a retention time corresponding to the first NMR signals of the dinucleotide. By means of this stopped-flow mode, it is possible to accumulate spectra for a longer period of time. This enables the acquisition of two-dimensional NMR experiments. These techniques are substantial in determining full-structure information on unknown compounds. As an example, the two-dimensional TOCSY

NMR spectrum of the adenosine dinucleotide is shown in Figure 3. In this spectrum cross-peaks indicate those protons which are coupled to each along an unbroken chain of couplings. Hence the coupling of each desoxyribose is clearly observable in two separate spin-coupling connectivities.

In 1999, a final improvement was made by Gfrörer *et al.* who coupled a gradient-elution CEC–NMR system to the interface. As an example, Figure 4 shows the CEC–NMR separation of paracetamol metabolites extracted from human urine. The result is viewed as a contour plot with the CEC separation time on the vertical axis and the chemical shift on the horizontal axis. The peaks that spread throughout the figure arise from the residual water and acetonitrile in the deuterated solvents of the buffer. In addition, sets of peaks related to paracetamol and endogenous material are observed. Those marked (1) can be assigned to the paracetamol glucuronide. Clear identification is possible via the diagnostic shifts of the glucuronic acid at $\delta = 3.8$ and 4.2. The component marked (2) is the paracetamol sulfate. The NMR spectrum of the third compound is consistent with the endogenous material hippurate (3). The appropriate individual rows taken from the contour plot are shown on the right-hand side of Figure 4.

Comparison of the Systems

Both types of NMR detection system have strengths and weaknesses. The substantial advantage of the solenoid system is its better sensitivity. The low detection limit resulting from the perfect filling factor of the system allows extremely small detection volumes. This is important for electrophoretic separations, where the peaks often have volumes in the order of a few nanolitres and larger detection cells thus limit separation efficiency. It is obvious that the arrangement is well suited for mass limited samples, but unfortunately the small detection volume is offset by the need for high sample concentrations. Typically, these have been $>30\text{ mM}$ but in some examples concentrations of $>50\text{ mM}$ were necessary, and this then leads to a limitation in the number of possible applications. The approach may need special sample injection techniques like the field-amplified stacking.

Another problem of the solenoid CE–NMR set-up is the complex interdependence on flow rate, electric field and current. The current, which passes through the capillary, produces a magnetic field gradient

that perturbs the uniformity of the main magnetic field of the NMR spectrometer. Large NMR line widths and reduced structural information are the consequences. High-resolution NMR spectra are only obtainable by periodic stopped flow capillary electrophoresis when the interruption of the current enables the acquisition of NMR spectra. However, this technique makes the already long separation times even longer.

The most important advantage of the saddle system is its easier handling capability. Already there is a large number and a wide range of reported applications to support this assertion. There are several reasons. Firstly, as described above, the capillary is arranged vertically in the saddle-type probe. Because the shim systems used for the field homogeneity adjustment in cryomagnets are optimized in the vertical z -direction parallel to the magnetic field, the shimming procedure is facilitated in comparison to the solenoid system. Furthermore, the coil is not permanently attached to the separation capillary, thus allowing the capillary to be easily exchanged for different applications without the risk of damaging

the rf coil. Finally the distance between coil and sample is relatively large and so problems with susceptibility do not occur.

On the other hand, the size of the saddle coil is problematic. Due to technical problems, it is not possible to reduce the coil diameter beyond a certain limit. To obtain a suitable filling factor, the detection cell has to be enlarged and the resulting detection volumes of 180–440 nL are much larger than in conventional CE and might be thought to lead to lowered separation efficiency of electrophoretic techniques. However, the fabrication method of these NMR cells produces cell profiles that avoid mixing and turbulent flows and thus the separation efficiency is not seriously compromised. Assuming a sufficient separation of the components large detection cells can even have advantages. Longer residence times of the components allow an improvement in the signal-to-noise ratio of the NMR spectra through the accumulation of an increased number of scans and the higher level of solvent reduces the necessary sample concentration to < 10 mM.

The two systems are complementary in approach and both have made contributions to a better understanding of the challenges involved in coupling CE and NMR. A decision on which type will find more widespread application will be determined by future improvements of the systems and possibly by the type of applications to which this technology will be applied.

Future Developments

Numerous obstacles to coupling capillary separation techniques with NMR spectroscopy have already been overcome. In the short term, the development is likely to be focused on the improvement of the NMR interface and a goal must be implementation of the advantages of solenoid and saddle systems. An interface that combines sensitivity and small detection volumes of the solenoid arrangement with the easy handling of the saddle-type configuration and thus allow routine and automated operations will find extensive use in the future.

One way to reach this goal might be the application of the new cryo-probe technology to capillary NMR spectroscopy. Such probes already exist for conventional NMR spectroscopy and provide, in favourable circumstances, an improvement in signal-to-noise ratio of approximately 400%. This is achieved by cooling the rf coil to reduce the level of thermal noise. This might increase the sensitivity of a saddle coil by a substantial factor without the need of a size reduction.

Another improvement would be integration of UV detection directly into the NMR probe. This would allow the performance of real stopped-flow measurements and this would, for example, circumvent the

problem of NMR line broadening by the electrical current for the solenoid interface.

Usually, capillary separation science techniques are optimized to handle minimal amounts of sample. However, because of the desirability of direct combination with NMR spectroscopy, new technologies have to be developed that allow an effective separation of relatively large sample amounts in small volumes without a reduction of the efficiency. There are many possible improvements, which are necessary in order to increase the capabilities of this new hyphenated technique. With forthcoming advances in the sensitivity of NMR spectroscopy, CE–NMR and CEC–NMR will become practical and useful methods in situations which require separation and structural determination of components of mixtures in severely mass-limited situations.

Capillary Gel Electrophoresis

R. Freitag, Swiss Federal Institute of Technology, Lausanne, Switzerland

Introduction

Electrophoresis covers a number of bioseparation techniques where charged substances are separated due to differences in migration speed in an electrical field. Since the 1950s, electrophoresis has been routinely used by biochemists to separate, quantify and identify large biopolymers, such as proteins, DNA and complex carbohydrates. In the early days electrophoresis was typically performed in slab or rod-shaped gels, which were necessary to hold the electrophoresis buffer and to minimize the dispersion of the analyte bands by suppressing convection caused by Joule heating and electroosmosis. At that time, electrophoresis was therefore commonly gel electrophoresis.

Electrophoretic separation is based on differences in the charge density (the mass-to-charge ratio) of the analytes. Small, highly charged molecules move faster than large, low charged ones, while uncharged molecules do not move at all. This is a powerful principle, for example for the separation of native proteins and peptides. Other biomolecules such as DNA restriction fragments and carbohydrates are very similar in chemical structure and therefore almost identical in charge densities. For these molecules gel electrophoresis represents a unique opportunity. Gels can be prepared to provide a sieving effect in the relevant mass range and thereby allow separation of charged molecules not according to their charge density but according to their size.

In 1981 Jörgenson and Lukacs published a series of landmark papers, in which they demonstrated both theoretically and practically how electrophoresis could be carried out in free solution as long as capillaries of small inner diameter were used and how the previously unwelcome electroosmotic effect could be used to advantage. The era of (free zone) capillary electrophoresis (CZE) began. Gels were no longer necessary, since the 'wall effect' in capillaries of less than 100 μm i.d. is sufficient to stabilize the flow. Capillary electrophoresis (CE) was seen as a complementary analytical technique to both liquid chromatography and 'conventional' slab/rod gel electrophoresis. In the following decade, research and application of free zone capillary electrophoresis ex-

ploded and several variants of the basic technique were established. In 1989 the first commercial CE instrument entered the market.

Capillary gel electrophoresis (CGE) was resurrected in 1983 by Hjerten, albeit for protein separations. It would probably have rested there, since protein CGE subsequently encountered severe problems. Instead it was the human genome project that helped to establish CGE as the important analytical technique it is today. The aim of this project is to determine the sequence of the over 3 billion base pairs that form the human genome. DNA sequencing requires the separation and identification of DNA fragments that differ in length by a single base. The progress of the project is largely determined by the speed of the respective analytical techniques.

The efficiency of CGE is extremely high and up to 3 million plates per metre are routinely reached. Heat dissipation is more effective in thin capillaries compared to conventional gels. As a consequence, much stronger fields can be used in CGE without loss in resolution. This results in significantly reduced analysis times. An example, the single base resolution of oligoadenylates containing from 12 to 60 nucleotides, is shown in **Figure 1**.

Current high throughput instruments use ultrathin capillaries and oligonucleotide primers that are covalently attached to different fluorescent dyes. The restriction digests of all four primers can therefore be analysed in the same sample. A comparison between CGE and conventional gel electrophoresis shows that even though more samples can be analysed in parallel in slab gels, CGE resolves a given sequence at least three times faster. **Table 1** summarizes some additional advantages and disadvantages of CGE over conventional gel electrophoresis.

Figure 1 Single base resolution of oligoadenylates containing from 12 to 60 nucleotides by CGE. (Adapted with permission from Baba Y, Matsuura T, Wakamoto K and Tsuchiko M (1991) *Journal of Chromatography* 558: 273–284.)

Table 1 Comparison of capillary and conventional gel electrophoresis*Advantages of CGE*

- Smaller sample volume
- Less buffer, gel and reagent consumption. The latter is especially important, since DNA gel electrophoresis requires toxic and/or mutagenic substances (e.g. ethidium bromide)
- Shorter analysis time
- Higher resolution
- Higher efficiency (over several million plates per metre)
- Reliable quantification of the analyte concentration by on column or off column flow through detector (UV absorbency, fluorescence, mass spectrometer, etc.) instead of staining and semiquantitative evaluation in the gel by densitometry
- Other than conventional slab gel electrophoresis, CGE can be fully automated from sample injection to separation, detection and data processing steps
- Semipreparative applications become much easier, since the molecules pass through and exit the capillary. In conventional gels, the zones are stained within the gel, from which they can only be removed by manual cutting of blotting

Disadvantages of CGE

- Restriction in sample size
- CGE gels are more difficult to prepare
- Capillary coating often necessary to reduce electroosmosis

Gel Filled Columns for Capillary Gel Electrophoresis

Cross-linked chemical gels and physical gels such as agarose are just as popular in CGE as in conventional slab gel electrophoresis. However, since the capillary wall effect exerts its stabilizing influence, solutions of entangled polymers are also used.

Naked fused silica capillaries show electroosmosis above a pH of 3. As a consequence the electrophoresis buffer flows towards the cathode. In capillary gel electrophoresis electroosmosis would lead to extrusion of the gel from the capillary. A possible way to avoid this is to coat the inner silica surface with a neutral polymer. Table 2 summarizes the more common types of capillary coating. Ideally, the coating should be effective in suppressing electroosmosis as well as the interaction of the analytes with the capillary wall. The preparation should be reproducible and the coating should be stable for a long time and over a wide pH range. Most coatings are attached to the wall by covalent bonds. However, dynamic coatings consisting of ionic, zwitterionic or nonionic molecules that are simply adsorbed to the wall either as monolayer or as bilayer are also used.

Chemical Gels

A general outline for preparing a cross-linked gel column for CGE is given in Table 3. Cross-linked polyacrylamide (PAA) gels are prepared by radical copolymerization of acrylamide as monomer and – most frequently – *N,N'*-methylenebisacrylamide (BIS) as cross-linker. $(\text{NH}_4)_2\text{S}_2\text{O}_8$ is commonly used as initiator in combination with *N,N,N',N'*-tetramethylethylenediamine (TEMED). Riboflavin (< 5 ppm) has been used as light sensitive initiator but requires the use of UV transparent capillaries. The polymerization of acrylamide can also be started by γ -radiation (^{60}Co source).

The resulting gels have well defined, fairly small average pore sizes of 2 to 8 nm. The %T, %C nomenclature is used for their characterization, with:

$$\%T = \frac{g_{\text{acrylamide}} + g_{\text{crosslinker}}}{100 \text{ mL solvent}}$$

corresponding to the monomer concentration:

$$\%C = \frac{g_{\text{crosslinker}} \times 100}{g_{\text{crosslinker}} + g_{\text{acrylamide}}}$$

corresponding to the crosslinker concentration.

Table 2 Common types of capillary coatings

Coating	Comments
Polyacrylamide with Si–O–C bond	Very common, easy to prepare
Polyacrylamide with Si–C bond	Improved hydrolytic stability, difficult to prepare
Polyethylene glycol	Very common
Nonionic surfactants	TWEEN and BRIJ series
LC type stationary phases	C ₁ , C ₈ , C ₁₈ , i.e. weakly, moderately and highly hydrophobic
GC type stationary phases	e.g. DB-17 (50% phenylmethyl silicone)

Table 3 Outline for the preparation of a cross-linked sieving matrix for CGE

Prepare stock solution of monomer, cross-linker, buffer, etc.
Cut/burn detection window if necessary
Pretreat the inner surface of the silica capillary (coating, activation, etc.)
Introduce mixture of monomer (cross-linker)/initiator/catalyst/stabilizing agent (if necessary)
Initiate polymerization
Pre-electrophoresis (to remove impurities and assure constant run conditions and a stable baseline)

Single strand oligonucleotides are typically separated in 2.5%T/3.3%C or 4%T/3.3%C gels. A higher cross-linker concentration gives a tighter sieve and thus higher size selectivity. An increase in the monomer concentration also results in a gel matrix with smaller pores. Lower %T/%C values result in a reduced selectivity but allow coverage of a wider analyte size range. An increased column length can compensate for the loss in resolution, albeit only at the price of increasing the analysis time. A reduction of the cross-linker concentration for a given monomer concentration results in larger pores. A 3%T/0.5%C gel has, for example, been found to give excellent resolution of double-stranded DNA restriction fragments varying from 5 to 12 000 base pairs.

Polyacrylamide is a popular gel matrix because of its electroneutrality. With time, however, it will be hydrolysed to charged polyacrylate, especially at high temperatures (high field strength) and extreme pH values. When the polyacrylate concentration becomes too high, an electroosmotic flow can be observed, which finally results in expulsion of the gel from the capillary. In order to prevent this, the gel may be covalently anchored to the wall coating. This calls for polymerizable (double bonds) groups in the coating. Alternatively, coating and gel formation can be done simultaneously in activated capillaries.

The preparation of gel-filled capillaries is not simple and only four out of five capillaries produced can actually be used. Problems arise in a number of areas, but a major cause of concern is the formation of bubbles during production, transport and use (injection!) of the gel-filled capillaries. Bubbles lead at best to loss in resolution and changing separation patterns and at worst to the total breakdown of the

electrical field, especially at high field strengths ($> 300 \text{ V cm}^{-1}$).

If the gel and the capillary wall coating are not physically linked, bubble formation is less of a problem, since the wall and the gel can move relative to one another. The reduced stability of the gel under these circumstances is another matter. Whereas capillaries with wall-bound gels can often be used for more than 100 runs, the number of separation that can be performed with the mobile gels tends to be an order of magnitude lower.

Bubble formation during polymerization is largely due to shrinkage of the gel during the process (higher density of the gel than the monomer mixture). **Table 4** summarizes approaches to circumvent this problem. In the case of the laterally aggregated polyacrylamide gels, a hydrophilic polymer such as polyethylene glycol (PEG) is added to the reaction mixture. The more hydrophobic PEG coordinates a large amount of water leaving the growing polyacrylamide strands to form hydrogen bridges mainly among themselves. As a result, thick gel fibres are formed and subsequently stabilized by cross-linking (**Figure 2**). The laterally aggregated gels have larger pores than homogeneous polyacrylamide gels of similar %T/%C. Their sieving behaviour depends also on the concentration and molecular mass of the PEG and should be determined experimentally in each case.

Physical Gels and Entangled Polymers

In physical gels the network structure is formed by noncovalent interactions such as van der Waals forces and hydrogen bonds rather than chemical

Table 4 Suggestions for the polymerization of bubble-free cross-linked PAA gels

Polymerization at high pressure (400 bar) to equalize the density of the monomer mixture and the final gel
Sequential polymerization starting with the gel formation at one end of the capillary and slowly progressing to the other, for instance by:
• irradiation (1 cm min^{-1})
• thermal (slow immersion into a heated water bath or slow removal from a cold one)
• isotactic polymerization (the initiator is placed between the leading and the terminating electrolyte and slowly moves through the capillary by isotachopheresis)

Laterally aggregated polyacrylamide gels (formed in the presence of a hydrophilic polymer such as polyethylene glycol)

Figure 2 Hypothetical model for 'laterally aggregated' gels. (a) Homogeneous network of cross-linked PAA. (b) Heterogeneous network of PAA in the presence of PEG 2000 (Reproduced with permission from Kuhn R and Hoffstetter-Kuhn S (1993) *Capillary Electrophoresis: Principles and Practice*, Springer Verlag.)

cross-linking. If large analyte molecules try to transverse this dynamic structure they also encounter a size-dependent resistance (sieving effect). The type and number of physical gels used in CGE is much more varied than the chemical gels. Mixed physical gels containing, for example, polyacrylamide and cellulose, are also possible. Both solid and liquid sieving matrices are known. Physical gels are often cheaper than chemical gels. They have a more flexible pore structure and can be operated at higher temperatures (50–70°C) and field strength (up to 1000 V cm⁻¹).

Examples of solid physical gels include agarose gels at room temperature and linear polyacrylamide gels with %T > 8 (the %C would be zero in this case). Such high %T polyacrylamide gels also have to be prepared by *in situ* polymerization. The size selectivity is a function of the polymer concentration and can be similar to that of the cross-linked polyacrylamide gels (Figure 3). Agarose is a natural polysaccharide network of 1,3-linked β -D-galactopyranose and 1,4-linked 3,6-anhydro- α -L-galactose. Purified agarose for electrophoresis can be obtained from a number of chemical suppliers. The matrix exhibits a wide range of pore diameters from several hundred nanometres to several micrometres and has high mechanical strength. Agarose is biologically inert and stable between pH 4 and 9. The gel liquefies around 65°C and solidifies again at 35°C. In the molten state it is easily injected into (or removed from) the capillary. Agarose gels can be used below and above the gelling point. Gel filled capillaries (0.3–5% by weight) are stable for a couple of days. No treatment of the capillary walls is necessary. To improve the stability of the gel a small amount of a polyalcohol such as sorbitol may be added.

Entangled polymer solutions are liquid sieving matrices. They are essentially low viscosity gels and can be replaced after each analysis. Hydrolysis or contamination of the network is thus less problematic. Gel formation in entangled polymer solutions de-

pends on the polymer concentration. In dilute solution the polymer molecules are hydrodynamically isolated. For a certain polymer volume fraction Φ^* (overlap threshold) the chains begin to entangle and interact. As a consequence a highly dynamic network is created. Experimentally, Φ^* can be determined by plotting the logarithm of the specific viscosity versus the polymer volume fraction. For $\Phi < \Phi^*$ the curve has a slope of approximately 1.0; for $\Phi > \Phi^*$ the slope increases.

Linear polyacrylamide has to be used at concentrations of at least 6%T to ensure sufficient size discrimination. The solution is then already very viscous and difficult to handle. Other hydrophilic polymers have much lower threshold values. The corresponding solutions are therefore less viscous and can be easily injected and replaced. Among them are various cellulose derivatives (overlap threshold approximately 0.3%), such as methylcellulose, hydroxymethylcellulose, hydroxyethylcellulose and hydroxypropylmethylcellulose. The sieving efficiency depends also on the molecular mass of the cellulose. Molecules weighing more than 900 000 g mol⁻¹ make good

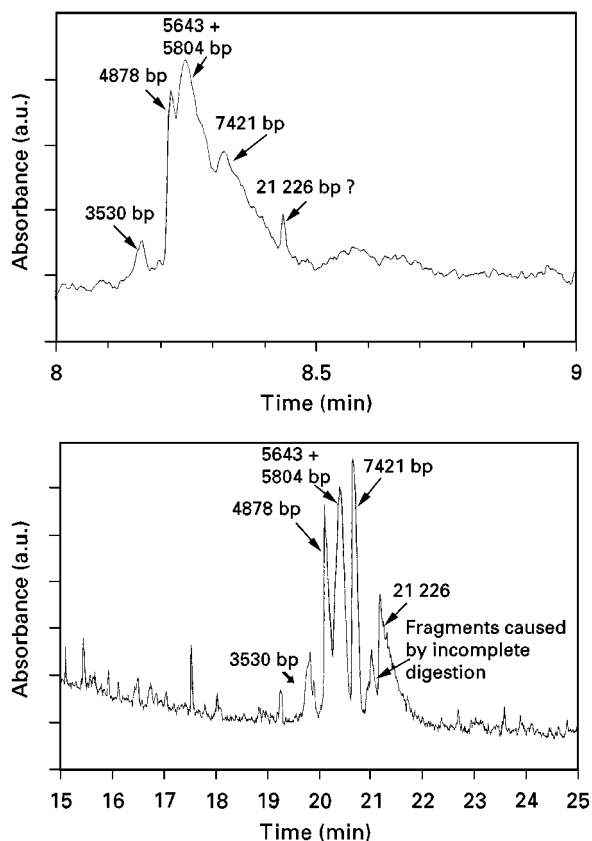

Figure 3 Separation of lambda-DNA restriction fragments (*Eco*RI). Top, 2% polyacrylamide gel; bottom, 4% polyacrylamide gel. (Adapted with permission from Hebenbrock K, Schügerl K and Freitag R (1993) *Electrophoresis* 14: 753–758.)

sieving gels for DNA fragments (polymer concentration 0.5%). For protein separation dextran or polyethylene rather than cellulose derivatives are used to prepare the gels. This has the additional advantage of allowing detection of the proteins at the more sensitive wavelength of 214 nm.

Both physical and chemical gels can be further modified, for example by the incorporation of cyclodextrins or antibodies into the matrix, to allow more specific interactions.

Separation in Capillary Gel Electrophoresis

Two models are used in CGE to describe the separation. The Ogston model considers the gel as a labyrinth of interconnecting pores and channels with an average pore (mesh) size of ζ . The analyte molecules are pictured as rigid spheres with a radius R . Small molecules can pass unhindered through a large fraction of the pores, they therefore move fast but larger molecules are slower. If the pore size of the gel is assumed to be a function of the polymer concentration, the following equations can be used to describe the situation:

$$\mu_g = \mu \exp[-Tb(R + r)^2]$$

and:

$$\mu_g = \mu \exp[-0.25\pi((R + r)\zeta)^2]$$

where μ_g is the analyte mobility in the gel matrix; μ is the analyte mobility in free solution for $E \rightarrow 0$; T is the polymer concentration; b is a constant; R is the radius of gyration of the analyte molecule and r is the average radius of the network pores.

The term $b(R + r)^2$ is also called the retardation coefficient, k . To obtain μ , the mobility of the analytes in free solution is extrapolated to a field strength of zero. A plot of μ_g versus T , the Ferguson plot, results in a straight line with a slope of k and an intercept of μ . This plot is used to determine the size separation range of the gel. If the plot is not linear, the assumption that the analytes are rigid spheres with a radius $R < r$ is no longer true.

Biopolymers are flexible molecules rather than rigid spheres and can therefore in reality pass through pores with radii of less than their own radius of gyration. The reptation model considers the analytes as dynamic and essentially chain-like structures that snake and wriggle headfirst through the network in a reptation (hence the name) type of motion. In this model the length of the flexible macromolecule is considered large in comparison to the distance be-

tween neighbouring knots in the network. The analyte mobility is proportional to the reciprocal of the chain length or, for nucleic acids, to the base number, N , of the molecule:

$$\mu_g \approx 1/N$$

Larger molecules are again more handicapped than smaller ones. For a flexible macromolecule the transition from the Ogston sieving model to the reptation model takes place when R becomes approximately 1.4 times ζ , depending on the nature (globular proteins, rod-shaped DNA molecules) and the flexibility of their structure. For very large molecules neither model holds true, because the electrical field deforms the molecular structure. For DNA fragments the equation is valid up to approximately 1000 base pairs, depending on the applied field strength. The mobility of larger DNA fragments is actually higher than expected. This leads to a co-migration of larger fragments with smaller ones, especially at high field strength and in high %T gels.

Instrumentation and Methodology

CGE requires no special instrumentation and can be carried out on the same type of instrument as standard capillary electrophoresis. All that is required in addition to the gel filled column is a high voltage power supply and a detector. Most commercial systems are automated to a high degree and also include an autosampler/injection module and a data handling station.

CGE uses continuous electrolyte systems. The separation of the analyte molecules is therefore a kinetic process. In general, all buffer systems for capillary electrophoresis can also be used in CGE. By far the most popular are TRIS-borate buffers (50 or 100 mM TRIS, 50, 100, 250 mM borate, pH 7.6–8.5, up to 5 mM EDTA), especially for the separation of DNA fragments and nucleotides.

While the separation of the native molecules is possible, denatured molecules are sometimes easier to analyse. In this case, denaturing agents, such as high concentrations of urea (5–8 M) are added to the separation buffer, in order to destroy the tertiary and quaternary structure of the molecules. A special case is polyacrylamide gel electrophoresis of proteins in the presence of the surfactant sodium dodecyl sulfate (SDS-PAGE). The protein structure is fully denatured under these conditions including cleavage of the disulfide bonds by a reducing agent such as mercaptoethanol. The remaining polypeptide chains bind SDS in a constant weight ratio (1.4 g SDS per gram of protein) to yield detergent-protein complexes of

Figure 4 Determination of the molecular mass of recombinant human antithrombin III. constant charge density. SDS-PAGE in slab gels is a standard method for purity control and mass estimation of proteins. SDS-PAGE in capillaries has been used for similar purposes (Figure 4). Ethidium bromide is a selective intercalating agent for double stranded DNA. The positively charged molecule can be used to optimize the separation of large DNA restriction fragments in CGE (Figure 5). It lowers the charge density and thereby the migration speed of the negatively charged DNA molecules.

Sample Introduction

Two basic types of injection principle are used in capillary electrophoresis. One is injection by pressure (vacuum suction or gravity), i.e. hydrodynamic injection, the other is electrokinetic injection. Pressure injection cannot be used with cross-linked gels, although it may be an option for some of the low viscosity entangled polymer solutions. In most cases it would either not succeed in pushing the sample into the capillary or destroy the gel.

For electrokinetic injection the capillary is placed into the sample vial and the electric field is switched on (typically between 1 and 20 s and 100 and 400 V cm⁻¹). The analyte molecules migrate into the capillary due to electrophoresis. Electrokinetic injection is biased towards small, highly charged molecules which are then over-represented in the introduced sample. In capillary gel electrophoresis the problem is less pronounced, since all analyte molecules are assumed to have identical mass to charge ratios, i.e. differ very little in migration speed.

The surface of the capillary inlet is very important (Figure 6). To ensure an even surface, the respective end of the capillary should be cut off with a microtome or snapped off cleanly after scoring with a sapphire cleaver.

Detection

The most common detection principles in CE are optical or column detectors (UV absorbance and (laser induced) fluorescence, LIF). Fluorescence and especially LIF detection allow very low limits of detection (LOD) to be reached. Unfortunately only a few biological molecules show native fluorescence. DNA molecules require pre- or postcapillary derivatization with a fluorescing agent, e.g. a fluorescence-labelled hybridization probe or primer. FITC, JOE, TAMRA, FAM and ROX have been used as labels in DNA sequencing. Proteins have been detected using their native fluorescence at 280 to 340 nm

(tryptophan residues). However, since the quantum yield is often low, labels such as fluorescein isothiocyanate (FITC 494 to 525 nm) are also used (Figure 7).

The problem with UV absorbance in CGE is the short optical pathway (inner diameter of the capillary), which leads to low sensitivity. Bubble and z-shaped cells can be used, but the bubble cell makes the capillary fragile, while the z-shaped cell lowers the resolution. In gel-filled capillaries the sensitivity suffers further because of the low UV transparency of most gels. The transparency of a PAA-filled capillary (6%T, 5%C) at 260 nm is 15% lower than that of a water-filled one; even lower if additives like urea or PEG are used. Instead of on-column detection, an off-column detector connected with a sheath flow interface can be used. In addition, several suppliers offer UV-transparent gels either of the cross-linked or the entangled type. The composition of these gels is usually proprietary.

Special Techniques

Varying the magnitude and the direction of the field, so-called pulsed field electrophoresis, can improve the resolution especially for DNA separation, since fragments of up to 10 million base pairs can be analysed. Since the larger molecules are assumed to snake through the gel, they need to orientate themselves in the field before they can advance. If the field is regularly inverted, the advance of the larger molecules is more affected than that of the smaller ones and as a consequence their separation is improved.

Voltage ramping has been shown to improve the separations of mixtures of small and large molecules. First high voltage is used to separate the smaller fragments, afterwards the larger fragments are separated with a gradually or abruptly decreased voltage. Field programming may also aid fraction collection, since the extremely sharp peaks of CGE are difficult to 'catch' unless the analyte migration is reduced by lowering the voltage.

Future Developments

CGE is a rapidly maturing technique and the need for high resolution bioanalytical techniques can be expected to increase rather than decrease in the near future. Up to now application of capillary gel electrophoresis has been dominated by DNA analysis. The potential of the method for protein analysis has not been realized. However, the demands of the modern biopharmaceutical industry for fast and reliable protein characterization techniques may soon change this.

The speed of CGE can be further accelerated by more stable gels (higher field strength) or by using several capillaries in parallel (array). If the sample size could be reduced further, the need for template amplification, e.g. by the polymerase chain reaction (PCR) would be reduced. Detection may be improved by increased use of high molecular weight mass spectrometers (MS). They can be linked to the CE instrument, for example by an electrospray ionization (ESI) interface. As these detectors become more affordable, their use in CGE will increase. Mass spectrometers combine a high sensitivity with being nearly universal detectors. When MS-MS is used more structural information of the analytes become available.

Capillary electrophoresis in many ways is already a microtechnique. However, further miniaturization is possible and the CE on a chip need not be far ahead. Such microchip CE will most likely use gel filled 'capillaries' to realize the maximum number of theoretical plates over the short separation distance.

Capillary Isoelectric Focusing

P. G. Righetti, University of Verona,
Faculty of Sciences, Verona, Italy
C. Gelfi, ITBA, CNR, Segrate, Milan, Italy

Isoelectric focusing (IEF) possibly represents the electrokinetic method with the highest resolving power. In IEF, amphoteric compounds are sorted in order of their isoelectric points (pI) in a steady-state pH gradient. Good resolution is favoured by both a low diffusion coefficient and a high mobility slope at the pI ,

conditions which are well satisfied by most proteins. A high field strength and a shallow pH gradient further enhance resolution. There are two basic variants of IEF: (1) in soluble, amphoteric buffers, called carrier ampholytes (CA) and (2) in insolubilized, non-amphoteric buffers (the latter technique is known as immobilized pH gradients, IPG). In this article we will deal with the former, i.e. CA-driven IEF, since IPGs have not as yet been implemented in capillaries. In fact, in IPGs, the buffers (acrylamido weak acids and bases) have to be grafted onto a support which at present is only a polyacrylamide gel. In addition, the gradient is created 'artificially', outside the electric field (whereas in CA-IEF the pH gradient has to be generated and maintained by the electric field itself), and thus gel casting requires the use of a two-vessel gradient mixer, with the simultaneous pouring of a density and a pH gradient in a flat-gel slab format. In normal use IPGs additionally require that the gel cassette is opened and that the polyacrylamide slab, with the grafted pH gradient, is exhaustively washed, so as to eliminate salts, ungrafted buffers and catalysts. This preparation sequence means that preparing an IPG in a capillary format is not a straightforward process.

The theory of IEF and IPGs, as well as the chemistry of the buffers adopted, has been covered elsewhere. Here we will focus on the techniques used in capillary IEF (CIEF), namely: one- and two-step focusing methods, pH gradient determination, sample preconcentration systems and some application examples.

General Considerations

CIEF combines the high resolving power of conventional IEF with the advantages of automation and speed. The separation of charged analytes takes place in a pH gradient created in a capillary by carrier ampholytes under the influence of an electric field. The concentrating effect that occurs during the focusing step, enables components present in small quantities to be detected. A major difference between IEF and CIEF is the detection method: in CIEF detection is performed in most cases with an ultraviolet (UV) or photodiode array detector placed near one end of the capillary. In order to visualize the stationary zones formed in the capillary, its content must therefore be mobilized in an additional step so that they pass in front of the detector window. To date, most of the reagents used in CIEF (carrier ampholytes, solubilizers and so on) have been adopted from traditional IEF. A number of reviews have already appeared on the topic of CIEF (see the Further Reading section).

A principal difference between IEF in a gel and in a capillary is that, in the latter, mobilization of the focused proteins past the detector has to be carried out if an on-line imaging detection system is not used. Three techniques are mainly used: chemical and hydrodynamic flow mobilization (in coated capillaries) and mobilization utilizing the electrosmotic flow (in uncoated or partially coated capillaries). These techniques are discussed further below.

Focusing in Internally Coated Capillaries

At any pH value above pH 2 the fused silica surface will progressively acquire negative charges due to ionization of weakly acidic silanol groups which are fundamental constituents of any vitreous material. Accordingly, close to the capillary wall (in the diffuse part of the double layer) there will be more positive than negative ions (electroneutrality will thus not prevail in the double layer). In an electric field, the hydrated, positively charged surface layer will move toward the negative pole, thus producing an electrosmotic flow (EOF), which can be observed as a bulk fluid movement. Such an EOF pump is not, in itself, deleterious to the analyte zone, since it has a flat profile (except in the few nanometre thickness of the double-layer); however, in the case of proteins, strong adsorption may ensue, due to multipoint attachment of positively charged species to the negative charges of the wall. In addition, particles migrating in directions opposite to the bulk liquid flow might never reach the detector. The electrosmotic mobility (μ_{eo}) is inversely proportional to the viscosity (in the double layer). Thus, by coating the inner surface of the capillary with a hydrophilic, non-ionic polymer, there will be two beneficial effects: the charges will be masked and, in general, suppressed and, additionally, the viscosity in the double layer will be so high as to virtually eliminate EOF. A typical coating consists in first reacting the wall with a bifunctional agent (γ -methacryloxypropyltrimethoxysilane) and then covalently affixing a monolayer of linear polyacrylamide to the dangling double bonds. Many other coating procedures have been described and have been reviewed by Chiari *et al.* (1996).

Focusing Step

The coated capillary is filled entirely with sample solution mixed into at least 1% carrier ampholytes (the sample should be desalted so as to avoid pH gradient drift). One end of the tube is then pressed into a 1% agarose gel, prepared either in 20 mM NaOH or in 20 mM phosphoric acid (representing

the cathodic and anodic solutions, respectively). The gel plug thus inserted into the tube end prevents zone-deformation by hydrodynamic flow in the tube during the subsequent focusing step. A constant voltage of 4000–6000 V is applied. When the steady-state has been attained, which occurs when the current has dropped to about 10–25% of the starting value, the voltage is switched off and elution started immediately as described below.

Elution and Detection Step

In such a system, due to suppression of EOF, the focused stack of carrier ampholytes and proteins is arrested; thus ways have to be found to transport the stack past the detector. A number of procedures can be adopted: (1) apply a mechanical pump to the capillary and generate a hydrodynamic flow (at the end of the IEF process); (2) replace the base at the cathode with acid or the acid at the anode with base and (3) salt mobilization. This latter technique has attained wide popularity. When a salt (e.g. NaCl) is added at the anolyte, mobilization will be towards the anode; conversely, if added to the catholyte, the train of bands will elute at the cathode. **Figure 1** shows

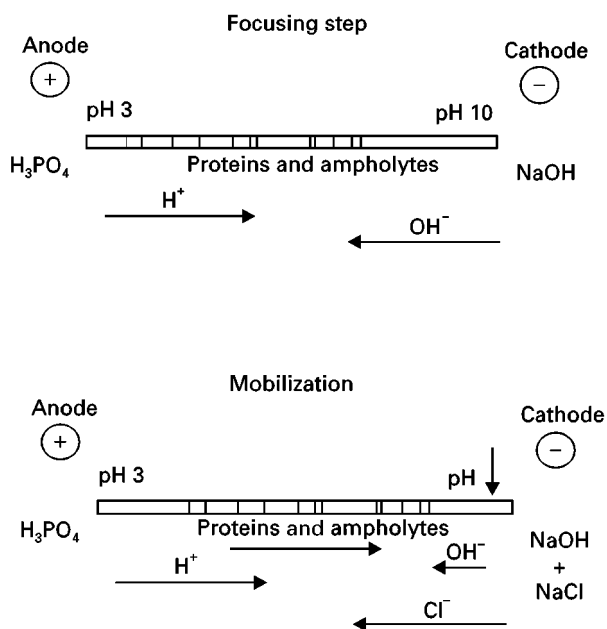

Figure 1 Focusing in internally coated capillaries. The focusing (upper) and mobilization (lower) steps. In the upper drawing the steady-state is shown as an arrested stack of proteins and CA buffers. Only protons and hydroxyl ions move from the respective electrodes carrying most of the current. In the lower drawing, addition of NaCl to the cathode is shown to mobilize the stack of proteins and CA buffers towards and past the detector port (represented as a large vertical arrow close to the cathode). (Reproduced by permission of Bio Rad, Hercules, CA, USA.)

a representation of this process: the upper part depicts the steady-state, characterized by a stationary pattern of focused proteins in an arrested pH gradient. In this stage, current is carried mostly by protons and hydroxyl ions moving from the anodic and cathodic compartments, respectively (and also by the to and fro movement of the CA buffers about the *pI* position!). On addition of the salt (typically 20–80 mM) at the cathodic reservoir, the stack of proteins and CA buffers is mobilized towards the cathodic side (past the detector). The time required for mobilization is about 15 min at 360 V cm^{-1} . During mobilization the current which had reached a minimum at the end of the focusing stage (typically $1 \mu\text{A}$) rises again to as high as $50 \mu\text{A}$. It is during mobilization that the train of zones, titrated away from the *pI* by the cations or anions (other than protons or hydroxyl ions) entering the tube from one of the electrode reservoirs, transits in front of the detector and is registered as a series of bands. Ideally, proteins and peptides should best be monitored at 210 (or even 190) nm where the absorbance of the amido bond is 20–50 times higher than at 280 nm. However, at the low wavelengths the CA buffers also produce a UV signal (rather similar for Ampholine and Biolyte, quite different in the case of Pharmalytes) which could be mistaken as sample zones. Thus, in an IEF experiment, it is best to read the sample at 280 nm.

Elution by Vacuum or Pressure Under Voltage

An alternative elution method consists in applying a vacuum of 5 mmHg while still under high voltage. The vacuum causes the focused proteins to flow past the detector, while the voltage maintains the pH gradient and zone sharpness even in the presence of distorting effects due to laminar flow. First, the entire tube is filled with NaOH (catholyte). Then, by hydrodynamic flow, approximately two-thirds of the capillary length is filled with carrier ampholytes. This is followed by a short sample plug, which is subsequently insulated from strong anolyte (which might, by contact, denature some proteins). At this point liquid pumping is stopped and the focusing process takes place between the phosphoric acid as anolyte and the NaOH as catholyte. Mobilization is again accomplished by a vacuum-driven hydrodynamic flow under voltage. The detection limit for proteins at 280 nm is as low as 1.3 ng, while the signal linearity is in the range of 1.3–10.7 ng (an eight-fold concentration range). Interestingly, this sensitivity is of the same order of magnitude as that reported for silver staining of sodium dodecyl sulfate-denatured protein zones and two to three orders of magnitude higher than conventional Coomassie Brilliant Blue staining.

pI Measurements

In its simplest approach unknown *pI* values can be assessed by plotting the *pI* values of a set of markers, co-focused with the proteins under investigation, versus their relative mobility on elution. This plot is linear and thus a high precision (approximately ± 0.1 pH unit) is obtained (see Figure 2). *pI* values as low as 2.9 and 2.75 can be determined. In another approach monitoring the current in the mobilization step can be adopted for *pI* assessments. If the peaks of the mobilized stack of proteins are monitored simultaneously with the rising current due to the passage of the salt wave in the capillary one can correlate a given *pI* value (which should already be known from the literature) with a given current associated with the transit of a peak at the detector port. The system can thus be standardized and used for constructing a calibration graph to be adopted in further work, without resorting to 'internal standards'. One such graph correlating current with *pI* values is shown in Figure 3: this appears to be a precise method, since the error is only about 0.03 pH units. The use of low M_r substituted aromatic aminophenols, which fulfil all the requirements for *pI* standards for CIEF and assure a 0.06% *pI* reproducibility, have also been proposed. In another method dansylated peptides have been synthesized for use as *pI* markers for evaluating pH gradient formation.

On Isoelectric Precipitation

Proteins have nett negative and nett positive charges at pH values above and below their *pI* values. This decreases the risk of aggregation, which ultimately

Figure 2 Calibration graph for *pI* determination using a set of marker proteins. The markers (open squares) are ribonuclease A (*pI* 9.45); carbonic anhydrase (*pI* 5.90); β -lactoglobulin (*pI* 5.1) and unsulfated cholecystikinin flanking peptide (*pI* 2.75). The four solid squares represent four unknown proteins whose *pI*s have been determined by linear interpolation in the calibration graph. Figure 3 Calibration graphs for *pI* determination using the current during the mobilization step as a parameter in capillary IEF. The six experimental points represent six forms of transferrin, containing different amounts of sialic acid and of iron. (Reproduced from Kilar F (1991) *Journal of Chromatography* 545: 403–406, by permission.)

may lead to precipitation. However, at, or in the proximity, of their *pI* value proteins exhibit a minimum of total charge and thus a solvation minimum. This increases the risk of aggregation, and is further enhanced by the extremely low ionic strength conditions prevailing in IEF. When protein molecules precipitate they probably aggregate by hydrophobic interactions. It seems logical therefore to try to suppress precipitation by supplementing the CA buffers with agents known to decrease hydrophobic interactions, such as ethylene glycol (10–40% v/v) or detergents (1–4% w/v). The detergents should be either non-ionic or zwitterionic, so as to be compatible with the focusing process; in addition, they should preferably be transparent at 280 nm so as to minimize interference with protein detection. There are some simple ways to reduce protein interaction and precipitation: one is to use dilute protein solutions (aggregation is proportional to protein concentration); the other is to increase the CA buffer concentration up to 4%, since this leads to an increase in total ionic strength. Conti *et al.* (1997) have investigated the use of a large number of solubilizers and proposed mixtures of mild agents capable of fully preserving the three-dimensional structure and full activity of biomolecules. Among the solubilizing agents are non-detergent sulfobetaines, taurine, Good's buffers such as bicine and CAPS, polyols, such as sucrose, sorbose, sorbitol and mixtures thereof.

The Detection System

As discussed above, the standard absorption wavelength for detection in IEF is 280 nm, the typical

absorption maximum of proteins. As an alternative method a universal concentration gradient imaging system not requiring a mobilization step can be used. This system is based on the Schlieren shadowgraph methods and uses a He-Ne laser to probe the capillary content and a charge-couple device (CCD) as a detector. The capillary has to be square, not covered by polyimide and rather short (4 cm). Focusing is completed in 2 min, resolution is of the order of 0.02 pH units and the mass detection limit appears to be of the order of the picomole level. As an alternative, a whole column UV absorbance detection consisting in transporting the entire column past the detector (the capillary, of course, has to be UV transparent) can be used. In this set-up the optical configuration consists of a 5 mW argon ion laser (with either a 496.5 or a 514.5 nm lasing line) probing the entire length of a 4 cm long, square glass capillary and using as a detector a 1204-pixel CCD camera. Focusing and imaging are usually completed in 2–4 min. The problem is that only coloured proteins (those that absorb in this wavelength region) can be efficiently detected (e.g. haemoglobin, myoglobin and cytochrome-c). Finally, a mass spectrometer has been proposed as a detector after CIEF: it should be noted that the technique becomes two-dimensional, since proteins are then mapped by both charge and mass.

Focusing in Dynamically Coated Capillaries

Three groups have reported approaches on the possibility of focusing in dynamically coated capillaries. The techniques will be reviewed below.

Dynamic Coating with Methylcellulose

Rather than completely eliminating EOF one might try to reduce it to such an extent as to allow attainment of steady-state conditions; from there on, the bulk flow would keep the 'arrested' stack moving past the detection window. This approach would then obviate the need for performing salt, vacuum or hydrodynamic mobilization; focusing and elution being accomplished in one step. A simple way for modulating EOF is to add viscous polymer solutions. The capillary can be conditioned with 0.1% methyl cellulose, mixed with sample and CA buffers and used to fill the entire column. It has been found that by increasing the anolyte concentration to 25 mM phosphoric acid also allows the detection of acidic proteins. Finally, it has been assessed how deleterious different amounts of salt (NaCl) present in the sample would be to the focusing process. As little as 10 mM

of NaCl in the sample suffices to entirely destroy the separation so salt in the analyte must be kept below this level.

Dynamic Coating with Hydroxypropyl Methylcellulose

In another system, the dynamic agent used for partial coating is hydroxypropyl methylcellulose (HPMC). In this approach, some interesting variants have been adopted. A new capillary is first rinsed for 20 min with 1 M NaOH and then for 10 min with 0.1 M NaOH containing 0.3% HPMC. It is during this final washing that conditioning of the capillary and partial coating with HPMC occurs. This etching procedure (with 1 M NaOH), followed by a short renewal of the dynamic coating (0.3% HPMC in 0.1 M NaOH) is shown to provide data of the highest reproducibility. The sample proteins are dissolved in 2.5% Ampholine solution, without any addition of HPMC. The anolyte is the standard 10 mM phosphoric acid solution, whereas the catholyte consists of 20 mM NaOH in the presence of 0.1% HPMC. The sample is introduced as a plug, occupying only 10–50% of the capillary length at the anodic side, the remaining being filled with catholyte. Since the entire stack of proteins will eventually be displaced towards the cathode by the EOF, this initial sample plug distribution allows more time to reach a good focusing pattern prior to sample passage in front of the detector.

Dynamic Coating with Adsorbed Surfactants or Polymers

In another variant, reduction of EOF via derivatization of capillaries with a hydrophobic coating (octadecylsilane) followed by adsorption of either a surfactant (Brij 35, PF-108) or a hydrophilic polymer (e.g. polyvinyl alcohol, polyvinyl pyrrolidone, methylcellulose) has been proposed. The procedure is as follows: the capillary is first treated with 1 M NaOH for 30 min, followed by several washings with deionized water and methanol (30 min each). The residual methanol is evaporated in an oven at 90°C for 2 h, while flushing the capillary with a stream of nitrogen at 400 kPa. While still in the oven at 90°C, a solution of octadecyltrichlorosilane in 50% toluene is flushed through the capillary for 6 h. After silylation, the capillary is rinsed for 20 min with methanol and then with water for 30 min. Surfactant solutions (in general 0.4%) are pumped continuously through the capillary for an additional 6 h in order to complete the coating process. Coating via adsorption of detergent (or methylcellulose 4000) is shown to reduce the EOF of the native, untreated capillary, to approximately 3–5% of the original value but the

residual EOF still allows adequate flow to obviate the need for a separate mobilization step. Based on the resolution of haemoglobin variants proteins that varied 0.03 pH units in isoelectric point were resolvable.

Sample Preconcentration Systems

Typical preconcentration steps commonly used in biochemical analysis (especially for macromolecules) such as lyophilization, ultrafiltration, partition between two polymer aqueous phases, osmotic removal of water and chromatographic adsorption-desorption, will entail large losses when the sample volume is 1–10 μL or less, as is customary in capillary zone electrophoresis (CZE). A number of electrophoretic methods for concentrating biopolymers (especially peptides and proteins), while partially depleting them of strong electrolytes (often a problem in all IEF procedures), have been described. In practice the whole electrophoresis tube is filled with the sample solution to be concentrated and then the sample is allowed to migrate against the end of the tube where a gradient of conductivity or viscosity exists and is arranged in such a way as to continuously slow down sample electrophoretic migration. The sample will finally collect in a narrow zone of the tube (typically 0.2–0.5 mm in width). A 400–1000-fold concentration is obtained when a 200 mm long tube is filled completely with the sample and still more if an electrode vessel is also loaded with sample. As an alternative, an on-line isotachophoretic (ITP) concentration process of very large injection volumes prior to CZE analysis can be adopted. Sample volumes up to 25 μL can be concentrated by this system. As concentrating large volumes would take a relatively long time, depending on the migration path length, a system of coupling a narrower bore to a larger bore capillary is generally utilized in order to speed up the process. Finally, after the ITP concentration step the sample can be analysed by CZE via a T-junction connected to another electrolyte reservoir (i.e. one has to resort to a three-pole column).

Some Application of Examples

A vast body of applications already exists; a number of them can be found in the reviews listed in the Further Reading section. We will consider some selected examples here. By using umbilical cord blood which contains only three major haemoglobin (Hb) components (Hb F, Hb A and Hb F acetylated, F_{ac}) it is possible to perform thalassaemia screening provided a good separation is obtained between Hb A and Hb F_{ac} , which have minute differences in pI values. In order to improve the separation the pH 6–8

Ampholine is admixed with an equimolar mixture of 'separators', namely 0.2 M β -alanine and 0.2 M 6-aminocaproic acid, which flatten the pH gradient in the focusing region of the three major components. Figure 4 shows this separation obtained by CIEF. The method is simple, can unambiguously detect any

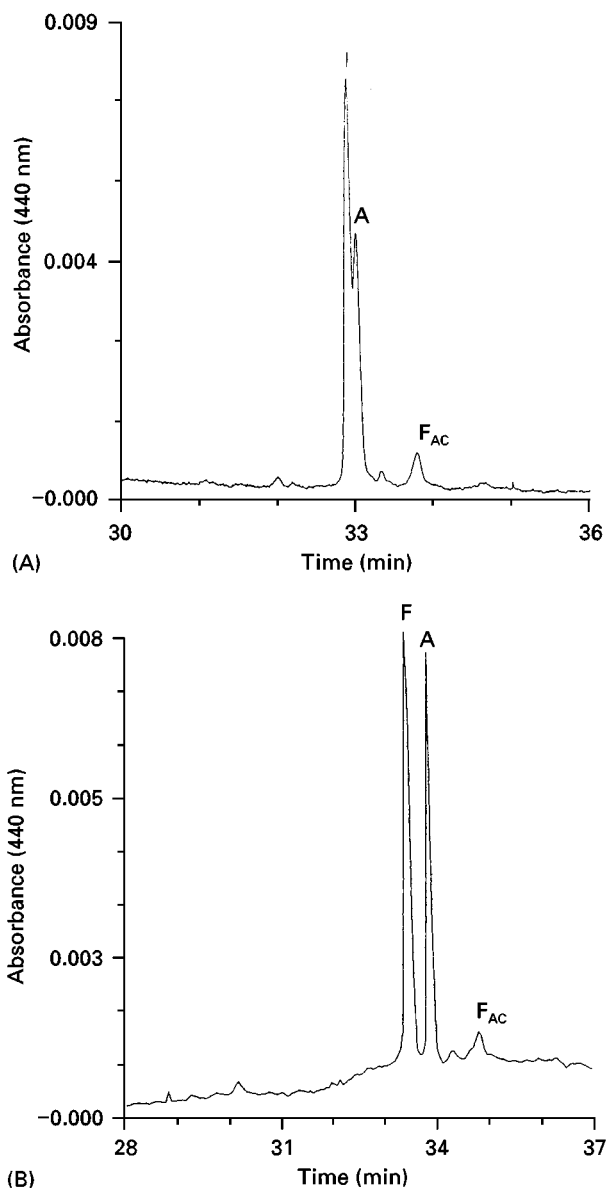

Figure 4 Separation of Hb F, A and F_{ac} by capillary IEF. Background electrolyte: 5% Ampholine, pH 6–8, added with 0.5% TEMED (panel A) and additionally with 3% short-chain polyacrylamide and 50 mM β -Ala (panel B). Anolyte: 20 mM H_3PO_4 ; catholyte: 40 mM NaOH. Sample loading: by pressure, for 60 s. Focusing run: 20 kV constant at 7 μA (initial) to 1 μA (final current), 20°C. Capillary: coated with poly(AAEE), 25 μm internal diameter, 23.6/19.1 total/effective length. Mobilization conditions: with 200 mM NaCl added to anolyte, 22 kV. Detection at 415 nm. (Reproduced from Conti M, Gelfi C and Righetti PG (1995) *Electrophoresis* 16: 1485–1491, by permission.)

thalassaemic condition and can be easily performed on a routine basis in a neonatal unit. Using the same principle Conti *et al.* have also attempted CIEF separation of Hb A from Hb A_{1c} (the glycated form of Hb A), the latter component being of diagnostic value for the long-term control of diabetic patients (glucose

Figure 5 Separation of Hb A from A_{1c} by capillary IEF in the absence (A) and in presence (B) of 3% short-chain polyacrylamide and an equimolar mixture of 'separators', 0.33 M β -Ala and 0.33 M 6-amino caproic acid. Background electrolyte: 5% Ampholine, pH 6–8, added with 0.5% TEMED. Anolyte: 20 mM H_3PO_4 ; catholyte: 40 mM NaOH. Sample loading: by pressure, for 60 s. Focusing run: 20 kV constant at 7 μ A (initial) to 1 μ A (final current), 20°C. Capillary: coated, 25 μ m internal diameter, 23.6/19.1 total/effective length. Mobilization conditions: with 200 mM NaCl added to anolyte, 22 kV. Detection at 415 nm. Figure 6 CIEF of a mouse monoclonal antibody using pressure mobilization. Focusing for 2 min at 10 kV, followed by mobilization at low pressure (0.5 psi) at (A) 10 kV and (B) 20 kV. Concentration of the marker proteins: 50 ng μ L⁻¹; concentration of desalted antibody: 0.5 μ g μ L⁻¹. Ampholyte solution: 4% Pharmalyte, pH 3–10, 1% TEMED in 0.8% methyl cellulose. Anolyte: 10 mM H_3PO_4 ; catholyte: 20 mM NaOH. (Reproduced from Schwer C (1995) *Electrophoresis* 16: 2121–2126, by permission.)

binds irreversibly to Hb molecules; the percentage of Hb A_{1c} varies with the blood glucose concentration to which red blood cells have been exposed during their circulating lifetime, see Figure 5). A good separation of monoclonal antibodies is shown in Figure 6: as mobilization was obtained by pressure under voltage it shows the importance of working under high voltage during this step.

Introduction

Isotachophoresis (ITP) is one of the fundamental electrophoretic separation techniques, where charged constituents are separated in an electric field due to their differences in their electrophoretic mobilities.

The moving boundary electrophoretic experiments and theoretical developments were the forerunners of isotachophoresis. Even by 1923, Kendall and Crittenden had described separation of some metals and acids by – as they called it – the ‘ion migration method’, which was in fact isotachophoresis. They concluded that ion concentrations were in accordance with the Kohlrausch regulation function. In 1942, Martin did his first experiments on what he called ‘displacement electrophoresis’ as an analogue of displacement chromatography. In 1963, Everaerts and Martin started their work on isotachophoresis. Up to 1970 several names had been used for what Kendall had called the ion migration method: these included the ‘moving boundary method’, ‘displacement electrophoresis’, ‘steady-state stacking’, and ‘ionophoresis’. In 1970, Haglund introduced a name, based on the characteristic feature of the electrophoretic technique, namely the equal velocity of the sample zones in the steady state: isotachophoresis (ITP). The basic theory and early development in the field of iso-

tachophoresis was described in 1976 by Everaerts in his fundamental book. An outline of the development of isotachophoresis is given in Table 1. Some advances in isotachophoresis are described in detail below.

ITP in Closed Systems

Up to 1990, ITP was carried out in commercial apparatus in 200–500- μm i.d. narrow-bore plastic capillaries and with closed systems, i.e. no electroosmotic flow (EOF) occurred.

Basic Theory

Under the influence of an applied electric field, E , ionic species will move towards the electrode with a migration velocity, v , of:

$$v = m \times E \quad [1]$$

where m is the effective mobility of an ionic species. The effective mobility depends on various factors, for example, the ionic radius, shape and charge of the ion, degree of dissociation, pH, dielectric constant and viscosity of the solvent, and temperature.

Typically, ITP is performed with a constant current and it is not possible to separate cations and anions in the same run (unidirectional isotachophoresis).

It is characteristic of ITP that the sample to be separated is injected between two different electrolyte solutions. The first solution (the leading electrolyte) contains an ion (the leading ion) with the same charge

sign as that of the sample ions, but with an effective mobility higher than that of the fastest moving sample ion. The second solution (the terminating electrolyte) contains an ion (the terminating ion) with the same charge sign, but with an effective mobility slower than that of the slowest moving sample ion. The polarity of the electric field has to be such that the leading ion migrates to the electrode that is placed on the same side of the sample as the leading electrolyte. After application of an electric field to the system, each ionic species will have a different migration velocity according to eqn [1] and hence the isotachophoretic process starts.

The process of isotachophoresis may be divided into two parts. In the first part, the separation of the ions proceeds and the migration velocity of the individual ions in the mixed zones is different. In the second part (in the steady state) the ions have already separated from one other and all move with the same velocity, v :

$$v = m_L E_L = m_i E_i = m_T E_T \quad [2]$$

where L is the leading ion, i is the i th ion and T is the terminating ion.

A schematic representation of the cationic and anionic modes in ITP experiments without EOF is given in Figure 1(A,B). As the ionic species are arranged in order of decreasing effective mobilities, the electric field strengths increase on the terminating ion side.

The increase in the electric field strength in the consecutive zones induces the zone-sharpening effect. When a zone has attained the steady state, the bound-

ary will not broaden further, which is in contrast to zone electrophoresis, where the peaks are broad owing to adsorption and diffusion. This effect can easily be explained. If an ion diffuses into a preceding zone, where the electric field strength is lower than the value that corresponds to its velocity, its velocity will decrease according to eqn [2], and it will be overtaken by its own zone. If an ion diffuses into a zone with a higher electric field strength, then it will obtain a higher migration velocity according to eqn [2], until it reaches its own zone.

It is characteristic for the steady state that the concentration of each component is adjusted to the value following from the Kohlrausch regulation function in the form:

$$c_i = c_L \frac{m_L + m_R}{m_L} \times \frac{m_i}{m_i + m_R} \times \frac{z_L}{z_i} \quad [3]$$

where R is the common counterion, Z_i is the ionic charge. In the steady state, the concentration C_i of the i th ion is always adjusted to a certain value depending only on the concentration of the leading electrolyte C_L and on the mobility of the ions i , L and R. From the analytical point of view this is a very important feature of ITP. It can be concluded that for a given set of experimental conditions, the zone length is a direct measure of the amount of an ion present in the zone. Another important consequence of these properties is the concentration effect of isotachophoresis. In fact, a species more concentrated in the original sample is diluted during the separation and, a species originally too dilute is concentrated during the separation.

Figure 1 Schematic representation of the two modes in unidirectional ITP experiments without EOF: (A) the cationic separation of a mixture of cations A, B, and C with $m_A > m_B > m_C$; (B) the anionic separation of a mixture of anions X, Y, and Z with $m_X > m_Y > m_Z$. The four modes in unidirectional ITP with EOF: (C) the cationic cations as in (A); (D) the anionic anions as in (B); (E) the reversed cationic; (F) the reversed anionic; (G) Schematic representation of the bidirectional ITP; separation of mixture of cations A, B and C and anions X, Y and Z. L_1 = leading cation; T_1 = terminating cation; L_2 = leading anion; T_2 = terminating anion. Only steady state is presented. S = sample inlet; D = detector position, L = leading ion, T = terminating ion, v_{EOF} = velocity of EOF; v_{ITP} = isotachopheretic velocity; \leftarrow or \rightarrow = net velocity; M = semipermeable membrane. For further explanation, see text.

In ITP, the response is usually recorded against time with a detector placed at the end of capillary (Figure 2).

The identity of a species is characterized by the effective mobility (or a quantity proportional to the effective mobility). This is usually the response of the universal detector. It is called the height (step height) or the relative height (relative step height, rsh) of the

zone, and is given by the relation:

$$rsh_i = \frac{h_i - h_L}{h_T - h_L} \quad [4]$$

where h_i is the step height of the compound, h_L is the step height of the leading ion and h_T is the step height of the reference ion (usually the terminating ion)

Figure 2 Graphical representation of response R from universal detector [(B) linear; (C) differential] for the different anions A, B, and C, moving in the steady state of an isotachopheric analysis (A). L = leading anion; T = terminating anion; S = sample inlet; D = detector position; M = semipermeable membrane. For further explanation, see text.

(Figure 2B). The values obtained in this way are then compared with those of standard species measured under the same experimental conditions.

The quantification is in general simplified by differentiating the signals and measuring the distance between the inflection point (Figure 2C). The zone lengths l_i are directly proportional to the number of ions (n_i): $l_i = K_i n_i$. The constant K_i depends on the equipment and the current used. A universal calibration constant (the response factor RF, eqn [5], which is independent of the diameter of the capillary, construction of the universal detector and driving current used during detection, has been introduced. For each component, the RF depends only on the concentration of the leading electrolyte:

$$RF = \frac{l \times I}{|z| \times F \times Q} \quad [5]$$

where l is the zone length (seconds), I is the driving current (amps), $|z|$ is the charge of the ion (equiv mol⁻¹), F is Faraday's Number (coulombs equiv⁻¹) and Q the amount injected (mol).

Based on the mathematical models for isotachophoresis described, computer programs have been set up for calculation of the parameters of the different zones. Unfortunately, only a few schemes

can be used for simulating capillary isotachophoresis at realistic current densities without causing either severe oscillations or unexpected program termination.

Online Coupling of ITP with CZE (Column-Coupling Instrumentation)

Column-coupling instrumentation (see below) of the separation unit for ITP as described by Everaerts has been shown to be suitable for online coupling of ITP and CZE. The extensive studies of Kaniánský and Marák give a good impression of the potential of combined ITP-CZE.

The online combination of ITP and CZE is a very effective tool for increasing the separation capability and sensitivity of CZE. It is characterized by isotachophoresis in the first capillary followed by online transfer of the sample cut into the second capillary where zone electrophoresis proceeds.

In principle, there are three ways of performing an ITP-CZE combination technique as far as the electrolyte systems are concerned. The simplest way is to use the terminating electrolyte as the background electrolyte (BGE) for CZE; the second possibility is to use the leading electrolyte as BGE and the third possibility is to use a totally different BGE.

ITP has the advantage of much higher loading volumes, e.g. microlitres instead of nanolitres in CE. In addition, ITP is a concentration technique. The combination of these features makes ITP, in principle, an ideal technique for sample pretreatment. In ITP-CZE, a 10⁴-fold concentration increase can be achieved, and this even for a component present in a 10⁵-fold excess of the matrix.

ITP in Open Systems

Since the early 1990s, commercial instruments for CZE have been available generally with open-tubular fused-silica capillaries with an inner diameter between 20 and 100 μm, together with an on-column detector placed towards one end of the capillary. As this apparatus can be used for ITP it was of interest to study the possibilities for ITP in open systems. If ITP experiments are performed in open-tubular fused-silica capillaries, the negative surface charge of untreated fused-silica causes an EOF towards the cathode. This EOF will influence the ITP system and four different modes can be observed. In Figure 1(C), the cationic ITP mode is shown. The EOF will generally act in the direction from the anode to the cathode and as a result the cationic ITP system will be pushed towards the cathode with a higher velocity compared with cationic experiments in closed systems. In

Figure 1(D), the anionic ITP mode is shown. This mode can be applied if the velocity of the leading ion is greater than that of the EOF during the whole experiment. Only in this case will anions with mobilities slower than that of the EOF also migrate to the anode according to the isotachopheretic condition. The reversed cationic mode (Figure 1E) can be applied if there is a reversed EOF (e.g. using coated capillaries or additives to the electrolyte) with a velocity greater than that of the cationic system. Here the cathode must be placed at the sample inlet end and the anode at the detector end. Although the ITP separation takes place in the direction of the cathode, there will be a net velocity of the ITP system in the direction of the detector end and components will be detected in a reversed order compared with a normal cationic ITP system. In Figure 1(F), the reversed anionic mode is presented. Here the anode is placed at the sample inlet end, the cathode at the detector end and components will be detected in a reversed order compared with a normal anionic ITP system.

As the velocity of the EOF is extremely important in the migration behaviour of ITP systems, much effort must be put into controlling EOF. The velocity of the EOF strongly depends on the choice of the leading and terminating electrolyte and it also varies with the composition of the sample. Moreover, the velocity of the EOF continuously changes during the analysis and is first determined by the composition of the leading electrolyte and finally by that of the terminating electrolyte. Varying EOF velocities cause irreproducible migration times and zone length and the results of quantitation are erroneous. The addition of methylhydroxyethylcellulose to the electrolytes and sample largely suppresses the EOF in order to improve quantitation. In spite of the addition of methylhydroxyethylcellulose, the reproducibility of the zone lengths with time is poor, and an internal standard is, therefore, needed. Hence the reproducibility in ITP quantitative analysis in open systems is a problem similar to that in electrophoresis. Generally, closed systems are to be preferred to open systems for quantitative analysis.

The presence of an EOF, however, facilitates the development of bidirectional ITP for the simultaneous determination of anionic and cationic components. In bidirectional ITP, the leading electrolyte for cations must be simultaneously the terminating electrolyte for anions, and vice versa the leading electrolyte for anions must be the terminating electrolyte for cations. That is, the counterions (cations) coexisting with the leading anions play the role of the terminating cation, and the counterions (anions) coexisting with the leading cations play the role of the termina-

ting anion. In a fused silica capillary in the presence of a cathodic EOF, cationic sample trains can be detected with a detector placed towards the cathodic end of the capillary. However, anionic species can be detected only at pH > 6. At pH > 6, the velocity of the EOF is greater than that of the anionic ITP system and hence the anions migrate slowest since they are attracted to the anode, but are still carried by the EOF towards the cathode (Figure 1G).

Instrumentation for ITP

Separation Capillary

The actual separation takes place in a PTFE (polytetrafluoroethylene) or a silica capillary. The separation capacity can be increased by extending the length of the capillary, but the analysis time and the maximum voltage required also increases. From the instrumental point of view, the column-coupling system (Figure 3) frequently used today has led to significant progress. It consists of a pre-separation unit with a capillary of larger diameter (e.g. 0.8 mm) equipped with the detector and bifurcation block, to which an analytical capillary of small diameter (e.g. 0.3 mm) is connected. At the beginning of the analysis, the driving current passes through the pre-separation capillary only. The detection system in the first capillary is employed to evaluate analysis. In addition, it provides the information necessary to control the transfer of the analytes into the second capillary and the removal of the sample constituents which are led out of the separation compartment after the first stage. At a suitable moment, the driving current is switched so that it passes through the analytical capillary and thus introduces the required sample zones into this capillary where further separation takes place. Column coupling enables use of different leading electrolytes in the pre-separation and analytical capillaries, thereby influencing the subsequent separation, separation of mixtures containing components in ratios up to 1 : 1000 without increasing the voltage and without prolonging the analysis time, and application of ITP in combination with CZE.

Electrode Chamber, Electrodes and Power Supply

The capillary is connected on each side to an electrode chamber provided with a platinum electrode. In closed systems, the chamber, filled with the leading electrolyte, is connected to the capillary via a semipermeable membrane. The terminator chamber is connected via a multiway switching valve, which is open in the course of the analysis. In open systems, the ends of the capillary are placed in electrolyte reservoirs (electrode chamber).

Figure 3 Column-coupling isotachopheretic system. EC = electrode compartment; BB = bifurcation block; D = conductivity detector; UV = UV detector; L = leading electrolyte; T = terminating electrolyte; M = semipermeable membrane.

A high-voltage power supply capable of delivering 500 μ A at up to 20–30 kV d.c. is needed. The constant current regulation of the power supply must be extremely well designed.

Injection System

In closed systems, the sample can be introduced by a microsyringe through a septum or by a multi-port valve system. In open systems, the sample can be vacuum-aspirated or loaded electrokinetically.

Detection

The first universal online detector was the thermocouple detector. Owing to its low sensitivity, the thermocouple detector was replaced with universal contact detectors, which sense the electrical resistance or potential gradient in the zones. The disadvantage of contact detectors is polarization of the sensing electrodes. To solve this problem, a universal contactless high-frequency conductivity detector was pro-

posed in the 1970s. Detection based on differences in the refractive index of various zones was introduced in 1981. The disadvantage of this system was the necessity of working with high electrolyte concentrations, which resulted in slow analysis.

In 1991, McDonnell and Pawliszyn developed a new refractive index detector for ITP consisting of a He–Ne laser or a laser diode and photodiode position sensor. The direction of the beam is deflected when it passes through the refractive index gradient produced by the sample zone. By using this detector, a few nanomoles of sample can be detected. The development of a selective UV-absorption detector for ITP had been an important contribution to the development of ITP in the 1970s. The UV detector is now a common component of commercial apparatus. In most cases only the wavelengths 254 and 280 nm have been utilized for detection. Arlinger had shown in 1974 that a UV detector could be applied as a pseudo-universal detector. UV-absorbing counterions were used, for which the molar absorption was pH-dependent. As each zone has its own defined pH and concentration, the pH and concentration difference gave rise to an absorbance difference sufficiently large to be detectable.

Sometimes it can be advantageous to use a UV-absorbing spacer in order to make the detection of consecutive zones of nonabsorbing ionic species possible. In some instances it is possible to detect boundaries between two consecutive non-UV-absorbing zones because of the trace amounts of UV-absorbing impurities which are present in most electrolytes and which concentrate as markers between the separated non-UV-absorbing zones. Great attention has been paid to development of new selective detectors for ITP, to facilitate the identification of compounds in the detected zones. Sensing of absorption spectra in isotachopheretic zones is one of the possibilities. Fluorimetric detection is a highly sensitive method. In ITP, the equipment designed initially for the dual-wavelength UV detection has been employed for fluorimetric zone detection. Zones of fluorescing compounds or of compounds quenching counterion fluorescence can be detected.

In 1991, Hirokawa introduced a new specific detection method for metal ions. He used an offline combination of ITP and particle-induced X-ray emission (PIXE), which is a multi-elemental method with high sensitivity. As the method is based on the characteristic X-rays emitted by target elements, it has a high specificity for the determination of the elements even if they are not separated. Radiometric detection of compounds labelled with a radioactive isotope is a specific method. Its principle is the detection of the radiation emitted from the labelled

compound zone passing the window of Geiger-Müller tube. Electrochemical detection, owing to its high sensitivity and specificity, is widely used in liquid chromatography. Its direct use in ITP is hindered by the presence of the driving electric field. To minimize disturbances due to the driving current, post-column amperometric detection has been employed. The separated constituents are hydrodynamically transported from the separation compartment into the detection cell. The hydrodynamic transport causes the dispersion to increase, therefore, the resolving power of post-column detection is lower in comparison, with for example, the conductivity detector. However, this disadvantage can be outweighed by its inherent selectivity and/or sensitivity.

The online combination of ITP with mass spectrometry was first demonstrated in 1989. The ITP/MS interface is based on electrospray ionization. Separations were conducted in open-tubular untreated fused-silica capillaries. The interface requirement of strong electroosmotic flow did not significantly degrade separations and both high sensitivity (limit of detection 10^{-9} mol L $^{-1}$) and high resolution can be obtained. Recently, Walker has demonstrated that a fiberoptic Raman probe can be used to obtain real-time intracapillary Raman spectra during ITP. Even at 2×10^{-5} mol L $^{-1}$ initial concentration, Raman spectra were obtained at a good signal-to-noise ratio.

Preparative Procedures in Isotachopheresis

Capillary isotachopheretic analysers can be used for preparative purpose in a discontinuous arrangement only. Once the separation has been performed, the analysis is discontinued and the analysed compound zone is isolated by using a microsyringe, a specially designed fractionating valve placed at the end of the separation capillary or a counterflow of leading electrolyte (Figure 4).

Continuous free-flow isotachopheresis (Figure 5) was developed to fractionate large-scale samples continuously. The separation field of continuous free-flow isotachopheresis is typically a thin film of fluid flowing between two parallel plates. An electric field is applied perpendicular to the flow direction. The leading and terminating electrolytes and the sample solution are continuously supplied with a multifold peristaltic pump into one end of the electrophoretic chamber and are collected with a multifold pump at the other. The leading and terminating electrolytes used for the electrode compartments circulate by pumps during migration. A dialysis membrane iso-

lates the separation chamber from the electrode compartments.

In recycling electrophoresis, in order to increase the electric charge applied to the sample, the fraction from each channel are continuously reinjected into the inlet port of the separation chamber. This instrumentation allows a high throughput and complete separation of the injected sample. Typical operation is batchwise, in contrast to continuous free-flow isotachopheresis.

Future Developments

Isotachopheresis underwent major development in the years 1970–1990. Over the last ten years CZE has occupied the major part of both the theory and applications of electrophoresis. Despite this, capillary isotachopheresis has kept its position as a special technique with unique features. Concentrating and

Figure 5 Continuous free-flow isotachopheresis. EC = electrode compartment; M = semipermeable membrane; L = leading electrolyte; T = terminating electrolyte; sample = mixture of A and B.

zone sharpening make it possible to obtain, in particular cases, much better results than when using CZE. Most promising is the combination of ITP with CZE where ITP serves as a preconcentration and pre-separation step for analysis of samples with complex matrices. Unfortunately, there is only one manual ITP–CZE system still commercially available.

The introduction of zone electrophoresis, pioneered by König in 1939, played a crucial role in the progress of electrokinetic separations. With this technique, molecules migrate as zones with sharp boundaries in a supporting medium immersed in a buffer solution under the application of an electric field. Zone electrophoresis was quickly found to be superior in performance to Tiselius's original technique of moving boundary electrophoresis and replaced it entirely – to be superseded in turn by displacement electrophoresis and isoelectric focusing (IEF). Interestingly, the term 'zone electrophoresis' was first suggested by Tiselius himself.

Kohn first used cellulose acetate (CA) as a supporting medium for zone electrophoresis in 1957, as a superior substitute for plain filter paper. Since then, CA has been used in many electrophoretic protocols, for both research and clinical investigations (Table 1). Nowadays CA electrophoresis is a widespread technique.

In this article we explain what CA is and why it is used in electrophoresis. This is followed by a brief overview of the uses of CA in various electrophoretic contexts. Finally, some recent and innovative applications of CA in electrophoretic protocols are discussed.

General Concepts

Preparation of CA

CA sheets employed in electrophoresis are made of a molecular matrix, similar in structure to a sponge but a thousand times smaller. This matrix is obtained by letting acetic anhydride react with cellulose and dissolving the product in an organic solvent, that can evaporate quickly. After letting the solvent evaporate in closely-controlled conditions of temperature and humidity, a highly permeable matrix is obtained with a uniformly distributed microporosity. The spatial volume of the pores may account for 80% of the total matrix size, ensuring ideal permeation by any

Table 1 Historical sequence of main applications of CA to electrophoretic protocols in different areas of research and clinical investigations

Year	Application
1957	CA is used as an electrophoretic support (Kohn)
1971	Application to conventional electrophoresis of white cell and red cell enzymes (Meera Khan)
1975	Application to isoelectric focusing of alpha-1-antitrypsin in human serum and 6-phosphogluconate dehydrogenase (Harada)
1984	Application to counterflow affinity isotachophoresis of antigens in biological fluids with low protein contents (Abelev and Karamova)
1992	Introduction of CA for protein transfer from polyacrylamide gels
1993	Introduction of protocols for reusing CA

electrolytic solution. When shaped into gel sheets CA has better resistance to the dehydration involved in the dissipation of heat and is more easily handled. Thus, pre-gelled CA membranes (also referred to as Cellogel™) are the first choice of support for many electrophoretic applications. For better handling, some commercial versions of Cellogel™ come welded to an inert support of polyester plastic (Mylar™). These commercial forms of CA pass practically unchanged through the entire separation–staining–destaining cycle of a classical electrophoretic experiment.

There are several major factors accounting for the versatile electrophoretic properties of CA: (1) the cellulose chain length, which ranges from a few to millions of individual molecules; (2) the degree of acetylation (from 0.1% to 44%); (3) the pore size (between 50 Å and 10 µm), the random pore distribution and the volume of the pores compared with the solid matrix (20% to 80%). The spatial coiling of cellulose molecules, the type and concentration of wetting agents and the presence of residual contaminants may also be important factors.

CA as an Electrophoretic Medium

Migration of molecules through the CA matrix depends mainly on the net charge on the molecule, the buffer pH and ionic strength and the intensity of the electric field. The difference in surface net charge between the molecular species in a sample to be separated is perhaps the most important point to consider. Proteins are amphoteric, like their constituent amino acids, and they may be charged positively or negatively depending on the pH of the solvent medium (the buffer solution, in an electrophoretic experiment).

In gel electrophoresis a sieving effect may affect the separation, depending on the critical relationship between the spatial shape of a protein species and the pore size of the matrix medium. Because of the extremely large cellulose matrix pores, the mobility of proteins in CA electrophoresis is a direct function of their surface net charge, whereas molecular weight and shape are less important. For example, the human heavy α -2 macroglobulin (M_r : 1 000 000; pI 5.9) moves faster than the much lighter haptoglobin (M_r 100,000; pI 6.1) in alkaline buffer solutions.

As in most electrophoretic protocols, to improve a CA separation the ideal buffer pH and ionic strength, strip temperature, voltage, current, electroosmosis and time of separation should be selected. The optimal ionic strength is between 0.01 and 0.1 (mequiv L⁻¹). Although mobility is theoretically enhanced at high temperature, proteins are easily heat

denatured so the separation temperatures should be kept below 50°C. Moreover, since CA electrophoresis is traditionally carried out with no cooling, separation voltages should not exceed 500 V (60 V per linear centimetre in gel strips), and the current should be adjusted to less than 2.5 mA cm⁻². CA contains polar groups – hydroxy (OH⁻) and acetyl (CH₃COO⁻) radicals – that become charged at the pH system and move towards the anode through the cellulose matrix. This produces a counter-reaction, displacing buffer toward the cathode and interfering with the separation of the molecules of interest (endosmosis). Prolonged separation times may thus lead to the creation of artefacts due to the combined effects of heat, buffer turbulence and the counter-diffusion of molecules. Running times should be altered accordingly.

A few fundamental properties make CA electrophoresis notably superior to electrophoresis using filter paper: (1) the CA matrix is homogeneous, microporous and chemically pure, reducing molecular adsorption to a minimum; (2) instant heat dissipation occurs in the matrix, which does not need to be cooled; (3) the amount of protein needed is very small (1 mg or less); (4) the inherent buffering–staining–destaining system is very simple; (5) stained CA strips have no background; (6) the standard electrophoretic apparatus required is simple and inexpensive (Figure 1).

For most purposes – especially for routine clinical investigations – small-scale CA electrophoresis (with membranes < 10 cm long) is widely used (Figures 2 and 3). Larger scale membranes (usually 20 cm long) suit a variety of research analytical purposes and micropreparative applications.

CA in Electrophoretic Protocols

Conventional Electrophoresis

CA was originally introduced as a classical support for analytical zone electrophoresis but found a much broader range of applications. Essentially, it can now be used for both analytical and preparative purposes. Preparative applications exploit the speed of CA separations, the absence of molecular interaction, and the easy recovery of biologically active substances from the matrix.

CA is popular in clinical laboratories in which some well-established routine analyses are performed, e.g. for haemoglobin, serum proteins, lipoproteins and lactate dehydrogenase. Isoforms of many enzymes and proteins from different tissues come out very clear-cut on CA – a fact that is (or has been) of particular interest for anthropogenetic and

Figure 1 Description of a universal electrophoretic apparatus for CA electrophoresis (redrawn and modified from Kohn, 1957). The CA strips (11) are supported at each end by the shoulder pieces (4) and when taut are just clear of the top edge of the centre partition (10). The top edge of this centre partition is formed as a row of pyramids (9) which support the strip should it tend to sag. When using long strips, strip supports (6) may be fitted to the labyrinth partitions (7) that form the connections between the buffer compartments (5) and electrode compartments (8). Filter paper wicks (3) connect the CA strips to the buffer compartments. The internal sides of the tank are stepped all round (2) as an aid to buffer level checking. The lid (12) fits in a recess (1) moulded all round the tank.

forensic purposes and for the biochemical characterization and classification of various pathogenic microorganisms such as *Leishmania* and *Trypanosoma* species.

In addition to one-dimensional electrophoretic methods, two-dimensional CA electrophoretic protocols are also available. A summary of important applications is given in Table 2.

Detection and Quantitation

Any protein stain can be used with CA, provided that the solution does not contain a cellulose solvent. Aqueous staining solutions are preferred to alcoholic ones, since with the latter strips tend to shrink and curl unless they are passed through an aqueous bath.

Staining solutions for CA are less concentrated than those used in filter paper electrophoresis, and they can be repeatedly used with no appreciable loss of sensitivity.

A wide range of analytical applications can be listed with an impressive variety of fully compatible staining methods, including Coomassie blue brilliant, Ponceau red, Nigrosin, Schiff, gold and silver stain, different types of immuno-staining, and many different types of enzyme specific staining. A 5% (w/w) aqueous solution of acetic acid is a universal washing solution for reducing the background.

The simplest way of evaluating the results is by visual inspection of stained strips, which should be carried out against a strong light source to improve the assessment of the separation pattern.

Figure 2 Electrophoretic separation of human haemoglobin variants A, C and S. Ponceau red staining was used to visualize haemoglobin bands, and the anode was on top.

Figure 3 Routine clinical electrophoretic separations on CA: (A) serum proteins; (B) lipoproteins; (C) Lactate dehydrogenase isoenzymes. Samples were obtained from healthy patients.

Quantitative determinations can be carried out by elution or by scanning of the stained strips. Once stained, protein bands can be easily eluted from the membrane by an appropriate buffer system (a classical system is Tris (2-amino-2-hydroxymethylpropane-1,3-diol) or Barbitone elution buffer over Ponceau red stained bands). Alternatively, a solvent (e.g. chloroform-ethanol 9:1 v/v) can be used to dissolve the membrane and recover the protein

of interest. To enhance the recovery efficiency, gelled CA blocks (about 0.5 cm thick, instead of much thinner 0.5 mm supports) can be used.

Scanning is preferred to elution for routine clinical applications. To reduce background and increase sensitivity, CA strips should be cleared prior to scanning. As with filter paper it is important to use oil with the same refractive index as the support. CA strips cleared with oil may be returned to their original dry state by using a solvent such as ether. By contrast, swelling agents such as acetic acid and dioxan used in conjunction with heat treatment, permanently clear CA.

Isoelectric Focusing

CA has ideal features to suit IEF separations. CA is virtually a non-sieving matrix enabling a quasi-free fractionation of macromolecules according to their respective isoelectric points (pI , the pH at which there occurs an equal number of negative and positive surface charges). CA is easily soaked with very small amounts of carrier ampholyte species, allowing them to be eluted in due course with no damage to stained-destained proteins; this in turn allows densitometry measurements and storage.

Unfortunately, the combined effect of CA electroosmotic flow and the low ionic strength of commercial ampholines can seriously impair the resulting separation of proteins at their isoelectric points. To overcome these drawbacks, CA has been variously treated with surface active agents or with methylating agents. Such treatments can partly – if not wholly – reduce the osmotic flow. Also, a high concentration of carrier ampholytes should be used to cover broad pH ranges (8% v/v instead of the customary 2% v/v) and electrolyte additives at low concentration (such as 0.2 M lysine and 0.2 M acetic acid) should help stabilize narrow pH intervals. Untreated CA strips give better results when 5% β -mercaptoethanol and 5 M urea are used as stabilizing agents.

Alternative strategies to circumvent electroosmosis, which differ in effectiveness, involve shortening the inter-electrode distance or using ‘chemical spacers’ to flatten the pH gradients at the appropriate segment of separation. These devices may help to create high field strengths with low voltages. Recently, thermoelectric cooling has been used to stabilize CA IEF gradients.

Counterflow Affinity Isotachopheresis

Isotachopheresis or ‘displacement’ electrophoresis permits simultaneous concentration and effective separation of surface-charged substances, including biological macromolecules. With this analytical method,

Table 2 Some recent applications of CA electrophoresis

Year	Application
1994	Introduction of thermocooling apparatus for CA IEF Sequential electrophoresis, with detection of 21 different alleles in ESD-2 locus in <i>Drosophila buzzatii</i>
1995	Improved separation of apolipoproteins by use of surfactant Tween 20
1996	Rapid screening of biochemical loci of rat Highly sensitive detection of urinary proteins using colloidal silver staining
1997	Detection of superoxide dismutase isozymes to distinguish between <i>tsetse</i> blood meals of human and non-human origin CA electrophoresis used as the method of choice for alpha-thalassaemia screening IEF on CA applied to the analysis of microheterogeneity of immunoglobulins and serum protein fraction

proteins are stacked as closely spaced, narrow bands between the 'leading' and the 'trailing' ions. Iso-tachopheresis on CA gels takes advantage of the absence of sieve effect in this matrix to study sets of interacting biological macromolecules, such as antigen/antibody and glycoprotein/lectin systems. However, electroosmosis once again interferes with this application. Abelev and Karamova were able to overcome this drawback by demonstrating that the cathodic counterflow, combined with the constant flow of liquid through the membrane, stabilizes separations. The counterflow may be also used as a 'conveyer belt' to move immunoreagents through antigens or antibodies immobilized onto the membrane. Abelev and Karamova used a discontinuous buffer system, in which the two buffers have the same cation and differ in the anion species (chloride as the leading ion and β -alanine as the trailing ion). Under these conditions, macromolecules are separated between the two anions.

Abelev and Karamova's method was originally developed to analyse proteins in highly dilute biological fluids such as urine, tears, and cerebrospinal and amniotic fluids, and it turned out to also be useful for detecting low levels of urinary monoclonal immunoglobulin light chains (Bence Jones protein) and alpha-fetoprotein in various pathological conditions.

CA as a Reusable Electrophoretic Support

CA separations are faster than those on other supports, usually with no resolution loss. However, CA sheets cost considerably more than starch, agar, agarose or polyacrylamide gel sheets.

Recently, a wash method has been described that makes it possible to recycle CA strips. The procedure has been shown to work even after using the strips for analysis of a variety of erythrocyte isoenzymes, which notoriously expose the support matrix not only to the strain of the electric field but also to many somewhat elaborate biochemical colorimetric treatment steps. Surprisingly, none of these stages seem to irreversibly affect the mechanical and physicochemical properties of the CA. In fact, after a variety of enzyme activity tests (adenosine deaminase, adenylate kinase, carbonic anhydrase, erythrocyte acid phosphatase, esterase D, glutathione peroxidase, glyoxalase 1, phosphoglucomutase and 6-phosphogluconate dehydrogenase) Cellogel™ returns to its original features if soaked/washed in water and methanol for a short time. In the course of double blind trials, no difference in band sharpness and resolution was noticed between new and used Cellogel™ strips. The procedure can be repeated two or three times if care is taken to avoid

warping strips with absolute methanol soaking or rough handling.

Blotting Proteins from Polyacrylamide Gels to CA Sheets

Different electrophoretic species run in the same gel for the same time with the same electric field settings. The end of a given experiment is currently set depending on the specific requirements of the molecules to be separated, in zone electrophoresis as well as in IEF.

To achieve optimal resolution of different protein constituents of the same sample, various experiments are often carried out, only differing in voltage and duration. To save time, a simple method involves repeatedly blotting a polyacrylamide gel with CA sheets at various stages of separation. The blots obtained in this way can be stained and the protein species made to show the optimal resolution.

The advantages that can be obtained from CA blots of the same acrylamide gel are great, the most outstanding being:

1. various stages of a single protein separation can be tested in one experiment, to improve the protocol;
2. common and rare variants of a single electrophoretic pattern can be detected, each under optimal separation;
3. several proteins can be analysed at optimal conditions in the same experiment;
4. all the allele products may be discriminated by isotachopheretic mechanisms (in non-equilibrium IEF) and isoelectric point (in true equilibrium IEF) within the same run.

Conclusion

Almost uniquely among the various supports for electrokinetic separations, CA electrophoresis is still intensively used for both research and routine applications. The reasons for this long-lasting success are clear: simplicity of use, low cost, versatility and cost effectiveness. These same factors are likely to provide the general basis for the continuing use of CA in the future.

Introduction

Separation of biochemical molecules can be carried out in gels or polymer solutions and, in specific cases, in free solution, using constant or variable electric fields. Gels are used primarily in deep-dish containers, submerged in buffer, and polymer solutions are used in glass capillaries, with inner diameters less than 100 μm . Thin gels between two glass plates have been used for separating and sequencing single-stranded DNA molecules. We begin the theoretical discussion by considering the separation of double-stranded DNA molecules (dsDNA) in submarine gels under constant electric field conditions.

Geometrical Sieving Model for Small DNA Molecules in a Constant Electric Field

Ogston was the first to calculate the fractional volume available to a sphere of radius R in a gel of a given concentration. The gel itself was modelled as a random array made up of fibres of radius r . Within this description, a sphere with a radius $R \gg r$ cannot pass through the network if the sphere is not allowed to deform. This geometrical model predicts that the electrophoretic mobility of DNA molecules, as a result of molecular ‘sieving’, varies as:

$$\frac{\mu}{\mu_0} \propto \exp \left[- \left(\frac{R_g}{a} \right)^2 \right] \quad [1]$$

where R_g is the radius of gyration of the DNA molecule, μ_0 is the free solution mobility, a is the average pore size of the gel, and the exponential dependence of the mobility arises from the assumption of Poisson statistics for the distribution of spaces in a random network of straight fibres. This model describes the mobility of small molecules when they first encounter the gel fibres as obstacles to molecular motion. The analysis of experimental data using eqn [1] is highly model dependent, but can provide some guidance for the development of new gel structures for more efficient electrophoretic separations of small molecules.

Entropic Trapping of Small DNA Molecules

For DNA in the entropic size regime, the deformable molecules select the larger pores in order to maximize locally their conformational entropy. However, in order to accomplish this, they must squeeze through the narrow channels connecting the larger pores. The corresponding polyelectrolyte dynamics is dominated by an activation process in this regime, where the electrophoretic mobility is given by an inverse power law (> 1) over a size range that is larger than for the Ogston regime, but smaller than for the beginning of reptation, which is discussed in the next section.

Gel Electrophoresis of Large DNA Molecules in a Constant Electric Field

Figure 1 shows a schematic picture of a gel matrix, in which a DNA molecule is embedded. For a molecule that is much longer than the average spacing between the chemical cross-links of the gel fibres, the molecule cannot move through the gel as a random coil, rather

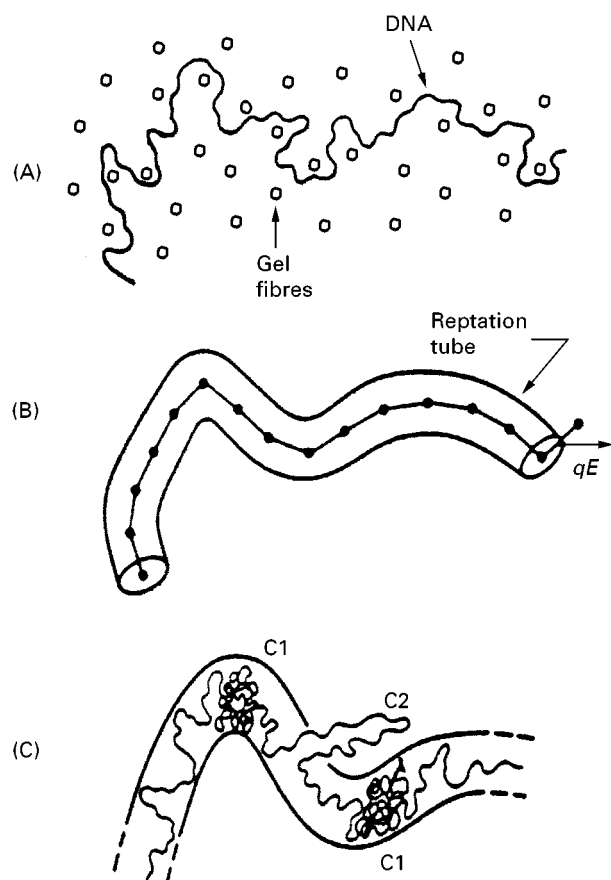

Figure 1 Schematic representation of a DNA molecule in a two-dimensional gel (A), in which the open dots represent obstacles corresponding to the gel fibres. (B) Shows how the obstacles hindering the motion of the molecule are approximated by a tube and the polymer by a chain of beads; the electric field exerts a force qE on the last bead and orients the segment leaving the tube. The tube is defined by the molecular conformation so that an extended conformation (with less DNA per gel pore) has a longer tube. (C) Charge gradients (C1) along the tube axis, and field-driven tube leakages (C2) are neglected in the biased reptation model.

it must reptate (from the Latin *reptare*, to creep) around the obstacles (cross-links), in a way that is analogous to the movement of polymer molecules in a self-entangled polymer melt. In this situation, the natural length scale is the average pore size of the gel, a . In terms of this length scale, we define a number of different quantities that arise in a theoretical description of the problem. One of these is the number of gel pore segments, N , occupied by the molecule:

$$N = \frac{M}{M_a} \quad [2]$$

where M is the relative molecular mass of the molecule and M_a is the average relative molecular mass in a gel

pore. Under the influence of an electric field, M_a can change as a function of time, depending on the stiffness of the molecule, the pore size, the magnitude of the electric field, and other factors. Another important quantity is the scaled effective electric field, E_{eff} :

$$E_{\text{eff}} = \frac{e_1 M_a E a}{2k_B T} = \frac{E}{E_a} \quad [3]$$

which defines the intrinsic electric field parameter E_a . The net charge per nucleotide for DNA is denoted by e_1 . This quantity depends on the native charge on the molecule, as well as on the charge screening properties of the buffer solution used for the electrophoretic separation. A simple way of understanding the limitations for separating large molecules in a gel using constant electric fields is as follows.

For constant a and M_a , the electrical force F_1 on the molecule in the longitudinal direction (also known as the tube axis, if the molecule is considered to fill a 'tube' made up of occupied gel pores) is:

$$F_1 = (qE) \cdot \left(\sum_i \frac{\mathbf{r}_i}{a} \right) \quad [4]$$

where $q = e_1 M_a$ is the average net charge of the molecule in a gel pore, and \mathbf{r}_i/a is the unit vector pointing from pore i to pore $i + 1$ along the molecule, where the dot in eqn [4] indicates the dot product of two vectors. This expression reduces to:

$$F_1 = qE \frac{h_x}{a} \quad [5]$$

where h_x is the end-to-end distance of the molecule in the field direction. The force is time-dependent and fluctuates during electrophoretic migration. Opposing the migration along the tube is a friction coefficient $\xi = \xi_0 N$, where ξ_0 is the friction coefficient per tube segment, as defined by eqn [2]. The instantaneous velocity of the chain along the longitudinal axis is then:

$$v_1 = \frac{F_1}{\xi} = \left(\frac{qE}{\xi} \right) \left(\frac{h_x}{a} \right) \quad [6]$$

and the average mobility of the centre of mass (defined as the velocity per unit electric field in the field direction) is given by:

$$\mu = \frac{\langle v_1(h_x/N) \rangle}{E} = \mu_0 \frac{\langle h_x^2 \rangle}{N^2} \quad [7]$$

where $\mu_0 = q/\xi_0 a$, and the geometrical factor (h_x/N) in eqn [7] takes into account the fact that the vector

h is in general not parallel to the direction of the electric field. For small electric fields and/or small molecules, $\langle h_x^2 \rangle$ proportional to N , giving μ proportional to $1/N$. In this regime the molecules reptate while retaining their random-walk conformations. For large molecules and/or high electric fields, the molecules become stretched in the electric field direction during migration, and $\langle h_x^2 \rangle$ is proportional to N^2 , resulting in a mobility that is independent of the molecular mass, according to eqn [7].

Figure 2 shows a log-log plot of the reduced electrophoretic mobility, μ/μ_0 , from Slater and co-workers as a function of the scaled molecular size, $N = M/M_a$, for different values of the scaled electric field. From top to bottom, $E_{\text{eff}} = 1.0, 0.2, 0.1, 0.01$. For small molecular sizes, the mobility is independent of the field intensity and decreases as $1/N$. For large molecular sizes, the mobility is independent of size and increases as E_{eff}^2 . The small minimum in the mobility is a phenomenon known as band inversion, for which, in a limited size range, large molecules can move faster than smaller molecules. Noolandi and co-workers have shown that this is a statistical effect where linear molecules, which have two free ends, can migrate into slowly moving 'J' or 'U' states for different time intervals, depending on the specific electrophoresis conditions. Since the bands of DNA molecules are not in order of increasing size in this

region, one has to be careful not to mislabel the molecular fragments.

In summary, the basic reason for the constant plateau mobility in Figure 2 is that for stretched molecules the electrical driving force and the opposing friction both scale linearly with length, and the resulting ratio is independent of length. For freely draining molecular coils in free solution, the same effect occurs, with the result that it is not possible to separate freely draining polyelectrolytes according to size in free solution electrophoresis. However, there are ways to overcome this limitation at least partly for free solution electrophoresis, as we discuss later. Next we turn to overcoming the limitations of constant field gel electrophoresis.

Pulsed Field Gel Electrophoresis of Large DNA Molecules

In constant field gel electrophoresis the maximum size of dsDNA that can be separated is about 50 kilobases. In pulsed-field gel electrophoresis separations up to a few megabases can be achieved. In this section we explain why such an increase in separation latitude takes place.

The plateau mobility is reached because of molecular stretching in a constant electric field. Schwartz and Cantor showed that the way to avoid this is to change the electric field constantly, either in magnitude and/or direction. The disadvantage of doing this is that it can take a long time to separate large molecules (separating dsDNA molecules a few megabases in size can take a few days). The advantage, of course, is that it is possible to separate large molecules at all, provided that the variations in the electric field are chosen properly. Changes in the magnitude and/or direction of the electric field force the molecules to adapt to the new electrophoresis conditions. However the adaptation time (also known as the 'relaxation' time) is very specific to the molecular size, average gel pore diameter, and electric field changes. It follows that there are a large number of ways to implement this process. Some pulsed-field gel separations use electric fields of the same magnitude and only change the field direction in two dimensions. Others keep the electric field in one dimension (forwards and backwards) for different time periods and with different amplitudes). We use the one-dimensional case developed by Turmel and co-workers as an example of how separations can be carried out by tuning the pulse times to the relaxation times of the molecules in the gel.

Figure 3 is a schematic illustration of the displacement of two types of molecules, molecular masses

Figure 2 Log-log plot of the reduced electrophoretic mobility μ/μ_0 as a function of the scaled molecular size $N = M/M_a$ for different values of the scaled constant electric field E_{eff} (see text). For small molecular sizes the mobility is independent of the constant field intensity and decreases with size as $1/N$. For large molecular sizes, the mobility is independent of size and increases as E_{eff}^2 . The electrophoretic mobility has a shallow minimum for intermediate molecular sizes.

Figure 3 Pulse shape for gel separations of large DNA molecules, using zero-integrated-field electrophoresis (ZIFE). As explained in the text, this pulse shape allows the proper size-migration distance to be maintained at all times, and gives rise to a sharp drop in the electrophoresis mobility as a function of size for fixed pulse parameters. For given electric field amplitudes, the reverse pulse time, t_- , defines the relaxation time of the largest molecule that can adapt to the lower electric field and have a net forward displacement during one complete cycle.

M_1 and M_2 ($M_1 < M_2$), when subjected to a high field forward pulse, followed by a low field backward pulse of longer duration than the forward pulse. During the pulse duration t_+ , with field intensity E_+ , the displacements of molecules M_1 and M_2 are $\mu(E_+, M_1)E_+t_+$ and $\mu(E_+, M_2)E_+t_+$ respectively, where the dependence of the mobilities on the field strength and molecular size has been explicitly indicated. During the reverse pulse of duration t_- , with absolute field intensity E_- , the reverse displacement of the shorter molecule is $-\mu(E_-, M_1)E_-t_-$, if t_- is long enough to allow the shorter molecule to relax to the new electric field in the backward direction. The net displacement of the shorter molecules over the time period $t_+ + t_-$ is then $\mu(E_+, M_1)E_+t_+ - \mu(E_-, M_1)E_-t_-$. However, for the longer molecule M_2 , the reverse displacement is $-\mu(E_+, M_2)E_-t_-$, if the time interval t_- is too short to allow the longer molecule relax to the lower electric field intensity E_- in the reverse direction. The net displacement of the longer molecule is then $\mu(E_+, M_2)E_+t_+ - \mu(E_+, M_2)E_-t_-$, and vanishes when $E_+t_+ = E_-t_-$. This is known as the zero-integrated field condition. With this condition the displacement of the shorter molecule becomes $[\mu(E_+, M_1) - \mu(E_-, M_1)]E_+t_+$, which is in the forward direction since $\mu(E_-, M_1) < \mu(E_+, M_1)$ if $E_- < E_+$. The zero-integrated pulse form allows the proper molecular size versus displacement in the gel to be maintained at all

times, avoiding the problem of band inversion. Although the tight DNA bands achieved by this process is an advantage, the running time for experiments is longer than for some other pulse schemes. Its usefulness depends on the specific requirements of the practitioner. The pulse times are determined experimentally using known molecular size markers, which show a sharp drop in mobility when the relaxation times are reached for a given size range. Using this information, a general electric field pulse scheme can be programmed for separating unknown DNA size distributions.

Capillary Zone Electrophoresis (CZE)

Capillary electrophoresis of DNA is a specific example of a technique used to separate molecules known as capillary zone electrophoresis (CZE), in which fused silica capillaries have their ends inserted in electrolyte reservoirs which also contain electrodes. This powerful analytical technique, as discussed by Gordon and co-workers, has been developed over the past decade in a number of different academic and industrial laboratories. Here the walls of the fused silica capillaries have a negative charge resulting from the ionization of the surface silanol groups in aqueous solution. When a potential difference is established between the electrodes, a bulk flow of fluid towards the cathode takes place. This is called electroosmotic flow, and results from the electrical double layer formed at the wall-electrolyte interface. The electroosmotic velocity is given by:

$$V_{eo} = \mu_{eo}E = \frac{\varepsilon\varepsilon_0\zeta E}{\eta} \quad [8]$$

where $\zeta = \delta\sigma/\varepsilon_0$, and μ_{eo} is the electroosmotic mobility, E is the electrical field, ε_0 the permittivity of the vacuum, ε the relative permittivity, ζ the zeta potential, η the viscosity, δ the double layer thickness and σ the surface excess charge density. The double layer thickness is inversely proportional to the square root of the molar concentration of the buffer solution. The electroosmotic flow enables the separation of charged molecules according to their different electrophoretic mobilities. In this method, positively charged molecules are eluted first because their electrophoretic motion and the electroosmotic motion are in the same direction. Negatively charged molecules try to move in the opposite direction, but if their electrophoretic mobility is less than the electroosmotic mobility, the net result is that they are eluted later than the positive molecules. Thus electroosmotic flow can be considered as a built-in pump which is useful for carrying out electrokinetic separations.

Clearly this process cannot separate neutral molecules if only an electrolyte is used. Sometimes micelles are dissolved in the separation electrolyte, resulting in some separation of uncharged species because of their partitioning between the micelles and the electrolyte. More commonly, one packs the capillary with a stationary phase, which can be bonded to the walls of the capillary, or formed by close packed small particles. The flow profile in the capillary has a nearly flat (plug-like) profile instead of the usual parabolic profile for Poiseuille flow when a viscous, incompressible fluid is pushed through a cylindrical tube by a pressure difference. The nearly flat flow profile makes the separation and detection of small amounts of analyte easier. This technique is known as capillary electrochromatography (CEC). The packing of the capillaries can be carried out electrokinetically, using commercially available small (a few μm) porous silica particles.

A number of different theoretical strategies have been used to increase the sensitivity of analyte detection. Programming of the electric field to achieve uniform sensitivity for on-line detection has been used, and theories for maximizing the signal-to-noise ratio for the case of laser-induced fluorescence and UV absorbance detection in capillary electrophoresis have been developed. In particular, for rather general conditions, the ratio of the number of fluorescent molecules in two analyte bands can be shown to be proportional to the ratio of the heights of the band peaks. This is useful for fluorescent analytes, and for cases where nonfluorescent analytes are labelled with fluorescent probes prior to detection.

Capillary Electrophoresis of DNA Molecules in Free Solution

In free solution the electrophoretic mobility of a free draining polyelectrolyte coil is equal to the ratio of its electric charge to its friction coefficient. Since both quantities scale linearly with molecular mass, the mobility is independent of molecular size. Hence the only way to separate molecules of different size in this case is to break the scaling symmetry of the charge and/or friction with size. As shown by Voelkel and Noolandi, adding a molecular unit with a different charge and friction to one of the ends of a linear polyelectrolyte, such as DNA, will change the free solution mobility to:

$$\mu(M) = \mu_0 \frac{M + q_{\text{eff}}}{M + \xi_{\text{eff}}} \quad [9]$$

where μ_0 is the free solution mobility of the unlabelled free draining polyelectrolyte, q_{eff} is the ratio of the

effective charge carried by the label expressed in terms of the charge per monomer unit of the polyelectrolyte, and ξ_{eff} is the friction of the label expressed in terms of the friction per monomer unit of the polyelectrolyte. In this approximation the hydrodynamic interaction of the label and the polyelectrolyte is neglected. The free solution mobility is now a function of the molecular mass. However the effectiveness of this strategy depends on the size of the label, compared with the rest of the molecule, and the amount of the band broadening caused by Brownian motion and other effects. In practice this approach seems viable for separating single-stranded DNA molecules up to several hundred bases long for DNA sequencing applications. While gel separations of single-stranded DNA molecules can routinely be carried out for sizes well over 500 bases, free solution separations, which are only effective for shorter fragments, can be carried out only an order of magnitude faster.

Capillary Electrophoresis of DNA Molecules Using Dilute Polymer Solutions

A separation mechanism that combines aspects of both free solution and gel electrophoresis is separation in capillaries using ultrathin polymer solutions. Here the DNA molecules drag along the polymer molecules that they encounter during migration. The capture and release of the unentangled polymer molecules results in the separation of DNA molecules. This new type of separation mechanism, developed by Barron and co-workers, is based on hydrodynamics, drag forces and molecular collisions, and is best suited for high throughput applications. The theoretical basis for the separation is still under development.

Capillary Electrophoresis of DNA Molecules Using Entangled Polymer Solutions

As pointed out by Slater, entangled solutions, as opposed to a gel, involve physical, instead of chemical, cross-links. For polymer solutions, we consider concentrations $c > c^*$, where c^* is called the critical concentration for entanglements:

$$c^* = \frac{M}{\left(\frac{4\pi}{3}R_g^3\right)} \quad [10]$$

M is the relative molecular mass, and R_g is the radius of gyration of the polymer molecule. For $c > c^*$ the polymer coils overlap and a loosely associated polymer network is formed. From the theory of polymer networks in solution we can characterize the mean pore size by a 'blob' dimension:

$$\xi = 1.4R_g \left(\frac{c^*}{c} \right)^{3/4} \quad [11]$$

However we must bear in mind that we are dealing with loosely associated networks, and that the physical cross-links are temporary, as opposed to chemically cross-linked networks. As discussed by Viovy and Heller, for low electrophoretic mobilities the dissociation and reassociation times of the network become important, because they occur on the same timescale as the transit time of the DNA molecules through the network. As a consequence, it is not possible to achieve better separations of DNA molecules through a concentrated polymer solution than through a gel, however polymer solutions are more easily processed (injected or removed) through capillary channels than cross-linked gels because of their low viscosities. Some polymer solutions have strongly temperature-dependent properties, which allows more latitude in the processing conditions.

Future Developments

Separations of biomolecules are being carried out on smaller and smaller devices, using miniaturized fluid-handling devices and detection systems. Making use of recent rapid developments in the area of microelectromechanical systems (MEMS), which exploits advances in microlithography for the semiconductor industry, new biochips and biosensors have been designed that enable faster analytical and diagnostic techniques to be carried out than was possible with macroscopic devices. As shown by Chee and co-workers, hundreds of thousands of DNA oligonucleotide probes can be assembled on a glass microchip, and combined with micromachined capillary electrophoresis injectors and separators. Complete hybridization patterns can be revealed in a matter of minutes, using laser-induced fluorescence. The implications for the entire biotechnology industry are revolutionary. Coupled with the knowledge obtained from the Human Genome Program, in which the estimated 100 000 human genes are in the process of being discovered and sequenced, thousands of genetic variations can be analysed in a single experiment, making possible the rapid localization of disease-causing genes.

From the theoretical point of view, there are several areas where advances are necessary to keep up with the rapid developments in instrumentation. First, new software codes are required to enable the rapid deciphering and processing of the massive amounts of bioinformation that are being generated. Second, detection systems with higher resolution than is currently available must be designed to interpret the spectral data that are available with the use of laser-induced fluorescence. Finally, theoretical modelling of the behaviour of electrolytes and biomolecules in microchannels in the presence of electric fields will be useful in understanding the ultimate capability of microdevices for the applications that we have mentioned.

Introduction

Polyacrylamide gel electrophoresis (PAGE) is a highly reliable and widely used technique for the separation, identification and characterization of proteins and protein mixtures. Although two-dimensional (2D)-PAGE, which combines protein isoelectric focusing (IEF) in the first dimension with sodium dodecyl sulfate (SDS)-PAGE molecular sieving in the second dimension, provides the highest resolution allowing one to separate 1000–2000 individual polypeptide spots on a single gel, 2D-PAGE is technically very demanding. However, in the vast majority of applications, one-dimensional (1D)-PAGE, specifically SDS-PAGE, provides sufficient resolution and is especially well suited for the simultaneous analysis of multiple protein samples on a single gel. Since its introduction in 1951, very few modifications to the basic protocols for preparing and running 1D-PAGE gels have been made, although considerable advances have been introduced for the detection and analysis of PAGE separated proteins.

Post-electrophoretic gel staining is the most frequently used method for the detection of individual protein bands or spots on 1D- and 2D-PAGE gels, respectively, although procedures for prestaining proteins prior to PAGE have been described. Detection is usually performed either *in situ* within the polyacrylamide gel matrix itself or following Western electroblot transfer of proteins from PAGE gels on to polymeric membrane support matrixes. Detection systems include organic dye and metal salt-based staining protocols, fluorescent group tagging, specific protein–ligand/receptor interactions, enzymic activity detection, as well as group-specific (e.g. glyco-, phospho-, lipoproteins, etc.) staining and immunological detection of antibody–antigen complexes. Alternatively, proteins which have been labelled with radioactive molecules, either prior to or post-electrophoretically, can be visualized using autoradio-

graphic and fluorographic detection on X-ray film. Although a plethora of protein staining and visualization protocols have been described, none is totally ideal and often the use of multiple protein staining and/or protein labelling procedures is necessary.

Protein Staining

Organic Dyes

Many of the organic dyes and stains that have been adopted for the detection of proteins in polyacrylamide gels and on membranes have been derived from dyes originally developed for the textile industry. Currently the most commonly used dyes include Amido Black, Procion Blue RS, Ponceau S, Alcian Blue, Fast Green FCF, Coomassie^{1,2} Brilliant Blue R-250 (R = reddish hue) (CBB-R) and Xylene Cyanine Brilliant G (confusingly referred to as Coomassie Brilliant Blue G-250) (G = greenish hue) (CBB-G). Recently, inorganic metal ion-based staining procedures have been developed that provide highly sensitive methods of protein visualization.

CBB-R and CBB-G are the most sensitive, convenient and economical to use of the commonly available dyes, and have become the reagents of choice for protein staining. CBB-R is a nonpolar, sulfated aromatic dye that is generally used in methanolic acetic acid solutions where excess CBB is removed from the gel matrix by destaining. An acidic environment is required for optimal CBB staining to enhance ionic interactions between the dye molecules and basic amino groups of the protein as well as to augment dye–protein interactions due to hydrogen bonding, van der Waals attraction and hydrophobic bonding.

¹ Any reference to a trademark or proprietary product does not constitute endorsement of that product by the US government and does not imply its approval to the exclusion of other products.

² CoomassieTM is a registered trademark held by the Imperial Chemical Industries (ICI). Equivalent CBB dyes under their own trademarks include Serva Blau (Blue) R or G, PAGE blue 83 (R) or 90 (G), Kenacid blue R, Supranocyanin 6B or G, Brilliant Blue R and Microme no. 1137.

Typically, CBB staining is performed using a 0.1–0.2% CBB-R (w/v) in aqueous (v/v) 45% methanol and 10% acetic acid. The duration of staining is dependent on gel thickness and polyacrylamide composition and destaining is performed using either passive diffusion or electrophoretic destaining. After destaining, gels can be stored in 7.5% acetic acid in which the dye–protein complex is fixed and the colour is relatively stable.

An alternative CBB-based procedure exhibiting very low background staining has been described using CBB-G. Incubation of gels in a colloidal suspension of CBB-G in aqueous trichloroacetic acid (TCA) results in the formation of dye–protein complexes, in which CBB-G interacts with proteins only at the surface of the gels and does not penetrate into the gel matrix, thus minimizing background staining. Major protein bands are visible within 5–10 min and for optimal staining of less abundant proteins gels should be left in the staining solutions for several hours to overnight followed by destaining in 5% TCA.

Amido Black (Buffalo black NBR, naphthalene black 12B, aniline blue black, naphthol blue black, acid black 1 and amido schwarz) was probably the first dye used to stain proteins in polyacrylamide gels; however, its use today is less frequent because of the availability of more sensitive CBB-based protocols. None the less, Amido Black still enjoys numerous applications because of its rapid staining and destaining properties.

A dye especially well suited for quantitation applications is Fast Green FCF (food green 3). Fast Green exhibits a greater linearity of staining as compared to CBB-R and also has the capacity to form stable coloured complexes with histones, thereby making it a useful group-specific stain. In contrast to CBB, Fast Green does not bind to carrier ampholytes and can be used for staining of proteins in IEF gels.

Recently, protein staining procedures utilizing calconcarboxylic acid *N,N*{1-(2-hydroxy-4-sulfo-1-naphthylazo)-2-hydroxy-3-naphthoic acid}, Eriochrome Black T/rhodamine B, Evans blue/rhodamine B, and CBB/Bismark Brown R have been introduced with reported sensitivity comparable or better than CBB in SDS-PAGE gels. A very useful general protein stain that also displays group-specific staining is Stains-all™, a cationic carbocyanine dye, which stains sialoglycoproteins and phosphoproteins blue and almost all other proteins red. Table 1 summarizes some of the more commonly used organic dyes for protein staining.

Silver Staining

For most applications, visualization of proteins with CBB is sufficiently sensitive. However, if one is inter-

ested in determining the absolute purity or trace amounts of a protein then more sensitive techniques must be utilized. To accomplish this, Merrill developed an ultrasensitive silver staining procedure based on photographic principles. Silver staining is upward to 100-fold more sensitive than CBB-R with sensitivity comparable to, or greater than, autoradiography, for selected polypeptides. It should be noted, however, that many proteins respond differently to silver staining. Some proteins may not stain at all, so sensitivity values for silver staining may vary from protein to protein.

Silver staining or silver shadowing procedures can be divided into three basic categories: diamine or ammoniacal silver stains; chemically developed nondiamine type; and photoreduction silver stains. The diamine or ammoniacal silver stains utilize ammonium hydroxide to form soluble silver–diamine complexes and proteins are visualized by acidification, usually with citric acid in the presence of formaldehyde. Diamine stains are rather time-consuming (overnight fixation and 6 h staining) but are particularly good for the staining of gels thicker than 1 mm. The nondiamine chemical development stains are generally more rapid than the diamine stains but display higher backgrounds and are best suited for gels 1 mm or thinner. Image development of nondiamine stains occurs as a result of selective reduction of silver ions to elemental metallic silver by formaldehyde under alkaline pH. The photoreduction silver stains are the most rapid, allowing the visualization of protein patterns within 10 min after electrophoretic separation; however, they are the least sensitive of the silver-based staining methods.

While most proteins stain monochromatically with silver, yielding brown or black spots and bands, certain silver stains can produce varying shades of black, blue brown, red and yellow and the staining of individual proteins appears to be group-specific. Lipoproteins tend to stain blue while glycoproteins appear yellowish-brown, or red. Colour formation has been shown to be highly dependent on the size and distribution of the silver grains within the gel as well as the refractive index of the gel and standardized colour-based silver staining kits are commercially available.

Reverse Staining

In contrast to the positive-staining procedure described above, alternative but generally less sensitive staining procedures based on the formation of insoluble metal (zinc, copper and potassium) salts have also been described. These methods, commonly

Table 1 Reagents useful for protein visualization on gels and membrane supports

Stain/dye	Sensitivity	Gel	Membranes			Comments
			NC	PVDF	Nylon	
<i>Organic dyes</i>						
Coomassie Brilliant Blue (CBB-R) and (CBB-G)	100–1000 ng	yes	yes	yes	no	Permanent, convenient to use, sensitive, anionic, relatively high background (CBB-R), (> 1 h) ^a
Ponceau S	1–2 µg	yes	yes	yes	no	Reversible, low background, rapid staining/destaining (<2 min)
Amido Black	1–2 µg	yes	yes	yes	no	Permanent, low background, anionic stain, stains histones and orosomucoids (>30 min)
India Ink (colloidal carbon)	80–100 ng	no	yes	yes	yes	Permanent, very sensitive, low background, sensitivity dependent upon source/lot of ink (>2 h), useful for charged nylon membranes
Fast Green FCF	1–2 µg	yes	yes	yes	no	Permanent, linearity of staining>CBB, does not bind IEF ampholytes, stains histones (30 min)
Stains-All™	1–2 µg	yes	yes	yes	no	General protein and nucleic acid stain, stains RNA (bluish purple), DNA (blue), most proteins (red) sialoglycoproteins and phosphoproteins (blue)
Periodic acid–Schiff (PAS)	25–100 ng	yes	yes	yes	no	General protein and glycoprotein stain. Silver enhancement increases sensitivity (~0.4 ng)
Procion Blue RS	1–2 µg	yes	yes	yes	no	Anionic, hydrophobic dye, occasionally used
Alcian Blue	500–700 ng	yes	yes	yes	no	Useful for staining glycosaminoglycan
Eosin Y	10 ng	yes	yes	yes	no	General protein stain, stains sialoglycoproteins
Congo Red	500 ng	yes	yes	yes	no	Low background, rapid (5 min), anionic stain
<i>Fluorescent stains</i>						
Dansyl chloride	100–200 ng	yes	yes	yes	no	Stains all types of proteins, including proteoglycans
SYPRO Red/Orange	100 ng	yes	no	no	no	Exhibits a greater linearity of staining than CBB, SDS-PAGE only, does not require protein fixation, will not stain nucleic acids
Fluorescamine	6–10 ng	yes	yes	yes	no	Neither fluorescamine nor its degradation products are fluorescent, low backgrounds
Fluorescein isothiocyanate	50 ng	yes	yes	yes	no	Rapid, can be used as pre-electrophoretic tag
Metal salt complexes						
Silver	1–3 ng	yes	yes	yes	no	Permanent, very sensitive, stains nucleic acids, hundreds of modifications, time-consuming
Colloidal gold (Aurodye™)	1–3 ng	yes	yes	yes	no	Permanent, very sensitive, silver enhancement increases sensitivity
Potassium chloride	10–100 ng	yes	no	no	no	Reversible, SDS-PAGE only, negative stain, whiter bands on opaque background
Iron (Ferridye™)	1–3 ng	yes	yes	yes	yes	Permanent, useful for nylon membranes
Copper (iodide/chloride)	10–100 ng	yes	no	no	no	Reversible, rapid (5 min), SDS-PAGE only, negative stain, clear bands on opaque background
Copper phthalocyanine	10–100 ng	yes	yes	yes	no	Reversible, rapid (<2 min), sensitive
3,4',4'',4''' tetrasulfonic acid						
Zinc/imidazole SDS	10–100 ng	yes	no	no	no	Reversible, metal chelate stain, SDS-PAGE only, negative stain, clear bands on opaque background, does not require protein fixation, protein eluted from gels with high efficiency (>90%)

^aStaining/destaining time. NC, Nitrocellulose; PVDF, polyvinylidene fluoride.

referred to as negative or reversible staining, are limited to SDS-containing gels and produce a semi-opaque background on the gel surface where proteins are detected as whiter or transparent bands or spots when viewed against a black background or when back-lit. Staining procedures are rapid (within 15 min), display intermediate sensitivity between that of CBB and silver staining, and since minimal protein fixation is required, proteins are readily eluted from gels (>90%) for biochemical characterization including Western immunoblotting, amino acid composition analysis and Edman N-terminal amino acid microsequencing.

Fluorescent Protein Labelling

Fluorescent methods for protein visualization are extremely sensitive but are less frequently used than the CBB/silver staining protocols due to their relative complexity (e.g. they require ultraviolet illumination for protein visualization, and fluorescence signal intensities diminish with time) and increased cost. Proteins can be tagged either pre- or post-electrophoretically with fluorescent sensitive dye(s) via covalent interaction of the dye with terminal $-NH_2$ groups of the proteins. Fluorophores most commonly utilized to label proteins prior to electrophoresis include dansyl chloride (1-dimethylaminonaphthalene-5-sulfonyl chloride), fluorescamine (4-phenylspiro(furan-2[3H]-1'-phthalan-3,3' dione), MDPF (2-methoxy-2,4-diphenyl-3-(2H)-furanone), DACM (N-(7-dimethylamino-4-methylcoumarinyl)maleimide) and OPA (o-phthaldialdehyde). Although dansyl chloride was the first fluorescent dye used for pre-electrophoretic labelling of proteins, fluorescamine has found increasing use since neither fluorescamine nor its hydrolysis products are fluorescent. Fluorescamine is capable of detecting as little as 6 ng of myoglobin while MDPF, which is 2.5 times more sensitive than fluorescamine, is very useful for quantitative applications and displays a linear staining response from 1 to 500 ng.

Proteins can also be detected post-electrophoretically using fluorescent reagents such as ANS (1-anilinonaphthalene-8-sulfonate), Bis-ANS, fluorescamine, *p*-hydrazinoacridine and OPA. Since labelling is usually performed under nondenaturing conditions, these reagents can be used quite advantageously for the rapid detection of proteins during preparative electrophoresis. Generalized procedures for both pre- and post-labelling with fluorescent dyes have appeared in reviews by Hames and Rickwood and Merril. Table 1 briefly summarizes the major metal-based and fluorescent dyes used to stain proteins on polyacrylamide gels.

Autoradiographic Detection

Labelling of proteins either prior to or post-electrophoretically using radioactive isotopes remains the most sensitive method for protein detection. Individual radiolabelled protein bands or spots are usually detected in one of three ways: liquid scintillation counting, autoradiography and fluorography. Modifications to facilitate the detection of proteins expressed at very low concentrations (e.g. transcription factors, cytokines, single copy gene products) or proteins labelled with low energy β -particle-emitting radioisotopes, such as [3H], include indirect autoradiography which utilizes intensifying screens for signal enhancement and fluorography.

Autoradiography

In autoradiography dried polyacrylamide gels containing radiolabelled proteins are placed in direct contact with the appropriate X-ray film (e.g. Kodak X-Omat AR, Kodak SB-5, Kodak BMS2, Kodak BMR2, Fuji RX) where radioactive emissions (β -particles and/or β/γ -radiation) react with the silver halides in the film emulsion, resulting in the formation of elemental silver atoms which are visualized following photographic development of the films. [^{14}C]-, [^{35}S]-, [^{32}P]-, [^{125}I]- and [^{131}I]-labelled proteins are readily detected using direct autoradiography while [3H]-labelled proteins are very weakly detected due to severe quenching of their low energy β -emissions by the polyacrylamide gel matrix.

Fluorography and Indirect Autoradiography

To enhance the detection of low abundance proteins and proteins labelled with low energy β -type emitters, fluorographic and indirect autoradiographic methodologies have been developed. Both procedures provide enhanced autoradiographic imaging of low to medium energy β -particle emitters (3H , ^{14}C or ^{35}S) and involve the conversion of the emitted energy from the respective isotopes to photons of visible light, which become the predominant exposing radiation. This is accomplished either by the incorporation of an organic scintillator, PPO (2,5-diphenoxoxazole), directly into the polyacrylamide gel matrix prior to fixation, drying and exposure to film (fluorography) or by the use of calcium tungstate X-ray intensifying screens (indirect autoradiography), as originally developed by Bonner and Laskey and Mills, respectively. For optimal sensitivity, film exposure utilizing X-ray intensifying screens such as Kodak X-OMATIC and Dupont Cronex Lightning Plus or Cronex Quanta II should be performed at low temperatures ($-70^\circ C$) to stabilize latent image formation. This results in up to a 30–40-fold increase in the

detection of [^{125}I] and 8–10-fold increase in sensitivity to [^{32}P]. Additional rare earths (europium-activated barium fluorochloride or terbium-activated mixtures of lanthanum oxysulfide and gadolinium oxysulfide) are available and these appear to be more efficient than calcium tungstate for [^{32}P] detection but result in higher background film darkening. The sensitivity of fluorography can be further increased by pre-flashing (< 1 ms) or hypersensitizing the film before main exposure. This step has the added benefit of correcting the so-called toeing effect or nonlinear relationship between the radioactivity in a sample to the absorbance of the film image, thus permitting quantitative measurements. If an autoradiogram or fluorogram is too faint then it is possible to intensify the images up to 10-fold by incubation of the X-ray film in [^{35}S]-thiourea which complexes with the silver ions in the film to form silver [^{35}S] sulfide.

Storage Phosphor Imaging

Two of the most serious limitations to the use of X-ray film for the visualization of isotopically labelled proteins are relative insensitivity to low energy β -radiation and a nonlinear, limited dynamic range of film darkening to radiation exposure. An alternative to X-ray film for the detection and quantification of autoradiography is photostimulable storage phosphor imaging. Storage phosphor imaging exhibits a dynamic exposure range of more than five orders of magnitude (100 000 : 1 versus 300 : 1 for X-ray film) and a 10–250-fold greater sensitivity than autoradiography to β -emissions. Dried gels containing radiolabelled proteins are exposed to imaging screens composed of a thin layer of $\text{BaFBr} : \text{Eu}^{+2}$ crystals in an organic binder in the same manner in which X-ray film is exposed. Incident radiation (β -particles, γ -rays, X-rays) from labelled proteins induces excitation of the Eu^{+2} ions in the phosphor complex which stores this energy as a latent image. The latent images are scanned with a helium–neon laser which releases the stored energy as blue photons and the intensity of luminescence is quantitated. [^{14}C], [^{35}S], [^{32}P], [^{33}P], [^{125}I] and [^{131}I] are readily detected and quantitated.

Labelling of Proteins with Radioactive Isotopes

The most commonly used isotopes include [^{14}C], [^{35}S], [^{32}P], [^3H] and [^{125}I], although metal isotopes such as [^{59}Fe], [^{45}Ca], [^{63}Ni] and [^{75}Se] have been used to identify iron, calcium and nickel binding proteins and Se-cysteine-containing proteins, respectively. Whereas [^{32}P]-orthophosphate has been used for the introduction of radioactive phosphate groups into proteins, the substitution of [^{33}P] for [^{32}P] has gained in popularity because of significantly increased res-

olution band sharpness as well as increased safety factors afforded by the lower energy [^{33}P] emitter as compared to [^{32}P].

In vitro metabolic labelling of cells or tissue sections in short term culture by incorporation of isotopically labelled amino acid(s) precursor molecules during the cellular growth phase is usually performed using either [^3H]-leucine or [^{35}S]-methionine/cysteine. The use of [^{35}S]- is favoured because of its higher energy β -emitter potential (0.167 vs. 0.018 MeV), higher specific activity (> 1000 vs. 50 Ci mmol^{-1}) and lower cost than [^3H]-labelled molecules. The extent of incorporation of [^{35}S]-methionine is, however, dependent upon methionine content of the individual proteins and proteins lacking methionine would be undetected using [^{35}S]-methionine labelling. This problem has been circumvented by labelling with [^{14}C] amino acid mixtures, although this method is less favoured due to significantly higher cost and lower specific activity (50 mCi mmol^{-1}) of [^{14}C] versus [^{35}S]. Proteins which are post-translationally modified via glycosylation can be labelled with [^3H]/[^{14}C]-galactose, mannose, N-acetyl-glucose and galactoseamine (carbohydrates), respectively, while lipoproteins and certain membrane-associated polypeptides can be labelled with [^3H]/[^{14}C] palmitate and myrisoylate.

Radioactive Stains

The use of radioactive stains for the *in situ* detection of proteins has found limited applications because of the availability of relatively few radiolabelled reagents. [^{59}Fe]-ferrous bathophenanthroline has been used to label radioactively a series of protein markers in polyacrylamide gels post-electrophoretically using simple staining and destaining procedures.

Protein Blotting

One the major advances in the analysis of proteins has been the development of post-electrophoretic techniques for the transfer and immobilization of proteins from the polyacrylamide gel matrix to thin support membranes. Originally based on DNA Southern and RNA Northern blotting principles, protein-blotting protocols were similarly developed by Towbin and co-workers utilizing the electrophoretic elution of proteins separated by PAGE to nitrocellulose (NC) sheets. The major advantage of protein electroblotting is that separated proteins are transferred from the gel matrix, where their access to detection reagents is severely hindered, to the surface of a membrane where the protein molecules are readily accessible. Although protein blotting has traditionally been associated with the immunodetection of

antigen–antibody complexes (Western immunoblotting), blotted proteins are amenable to analysis and characterization via a multitude of visualization and overlay techniques. These include general protein staining and autoradiography, group-specific ligand binding, receptor–ligand interaction, enzymic activity determination as well as amino acid composition and primary amino acid sequence analysis of individual spots or bands. A single protein blot offers numerous advantages not afforded by polyacrylamide gels. It is easily handled and manipulated, can be stored for up to 1 year and the blot can be used for multiple successive analyses. Once a signal has been obtained and recorded, the blot can be erased by removing the probe or stain while retaining the original protein pattern on the membrane and the blot reprobed. Protein blotting has been said to add a second and third dimension to 1D and 2D-PAGE, respectively.

Various types of membranes have been used for protein blotting and immobilization. Nylon and NC sheets (thin film on cellulose esterified with nitric acid) were first used but recently different types of polyvinylidene fluoride (PVDF) membranes have been introduced. A detailed description of protein-blotting methodology, including the advantages and disadvantages of the various blotting membranes, is beyond the scope of this article (see Further Reading).

Immunological Detection

Immunological or group-specific detection of protein(s) on blotted membranes is far and away the most utilized method for protein detection but is limited by the availability of appropriate antibodies/ligands. Following protein transfer, membranes are incubated with dilute protein solutions (e.g. bovine serum albumin, gelatin or instant nonfat dry milk) to block nonspecific binding sites on the membranes. The membrane-bound proteins are incubated with either monoclonal or polyclonal antibodies directed against specific target antigens or group-specific ligands (e.g. Concanavalin A for the detection of glycoproteins, ^{59}Fe and ^{45}Ca to detect iron- and calcium-binding proteins, and [^{32}P]-labelled DNA to detect DNA binding proteins). NC and PVDF membranes are most frequently used since nylon membranes with their intrinsically higher binding affinity for proteins are more difficult to block. If antibodies are used, then blots are incubated with a second antibody that has been directed toward the primary antibody and has been tagged with a reporter label. Typically, the second anti-species antibody may be radiolabelled (^{125}I) or conjugated with an enzyme (e.g. horseradish peroxidase (HRP), alkaline phosphatase (AP) or β -galactosidase). The resulting (antigen–1 $^{\circ}$ antibody)–2 $^{\circ}$ antibody complex is detected

either autoradiographically or colorimetrically using an appropriate chromogenic substrate. The advantages of enzyme-conjugated antibodies are ease of handling and storage and rapid development of colour (min vs. day). Sensitivity is usually in the range of 0.1–10 ng of antigen/band. While this sensitivity is approximately 10–100-fold less sensitive than autoradiographic or fluorographic detection, it is possible to achieve a similar level of enhanced sensitivity using peroxidase–antiperoxidase (PAP) sandwiching.

Recently, modifications have been developed for the use of light emission (luminescence) as an end point for protein–antibody detection on membranes. Although substrates which produce colour complexes exist for both AP and HRP, the HRP luminescent system, in which blue light is generated by the HRP-mediated oxidation of luminol, is the most sensitive system. This system, commonly known as the ECL (enhanced chemiluminescence) Western blotting system, provides excellent signal-to-noise ratio and is extremely rapid and sensitive.

In the basic (nonenhanced) chemiluminescent reaction, HRP is used to oxidize a peracid, resulting in a raised oxidation state of the haem Fe in HRP. Relaxation of this excited state to initial (ground) state occurs in a two-step process. At each relaxation a luminol radical is formed and, as each radical decays, light is emitted. However, in the ECL reaction, an enhancer molecule is added which reacts with the haem Fe in place of the luminol molecule, resulting in the formation of enhancer radicals which themselves react to produce luminol radicals and light is emitted. The enhancer molecules increase light emission greater than 1000-fold over luminol alone. Light emission on membranes rises rapidly over the first 5 min, remains at maximum for 15 min, and then declines with a $t_{1/2}$ of 60 min. Typical exposures for ECL are of the order of a few seconds to minutes and are capable of detecting 1 pg or less of protein.

Total Protein Staining

Blotted membranes can be stained with many of the general protein stains used for polyacrylamide gels including Amido Black, CBB, Ponceau S, Fast Green and India ink (Table 1). Amido Black and Ponceau S are preferred to CBB-R because stained membranes can be destained quickly to leave very low backgrounds, whereas CBB-R gives higher backgrounds. India ink (colloidal carbon) is the most sensitive of the above dyes and can detect as little as 80 ng of protein but staining sensitivity is highly dependent upon dye source and lot. Silver staining is also possible as well as the use of colloidal gold and iron sol stains. Both silver and gold stains can detect as little as 1–5 ng protein on NC and PVDF membranes and

the sensitivity of gold stain can be further enhanced by incubation with a silver lactate solution such that as little as 400 pg of protein per band can be detected. Although nylon or charged nylon membranes possess the greatest protein-binding capacities (450 vs. 80 $\mu\text{g cm}^{-2}$ (NC/PVDF)), staining of nylon membranes is very problematic. Anionic organic dyes as well as colloidal gold and silver are not useful for staining nylon membranes due to extremely high backgrounds. However, colloidal sols are especially useful for the detection of proteins on nylon membranes. On nylon membranes the positively charged colloidal iron particles bind to negatively charged SDS-denatured proteins and protein staining can be intensified using potassium ferricyanide, which gives deep blue-stained bands with low backgrounds. India ink and a modified silver stain have been reported to have been used to stain charged nylon membranes.

A less frequent, but none the less useful method for the visualization of protein bands on NC and charged nylon membranes involves protein iodination *in situ* with chloramine T/potassium iodide, followed by formation of a purple complex between the bound iodine and starch.

Autoradiographic Detection

Electroblotting of proteins radiolabelled with ^{14}C or ^{35}S permits more efficient autoradiography since the gel matrix is no longer present to quench the β -emissions. The minimum level of ^{14}C or ^{35}S that can be detected in 24 h is about 400 dpm cm^{-2} . While fluorography is necessary to detect ^3H on polyacrylamide gels, ^3H exposure can be detected directly on electroblots using autoradiography, although 2×10^4 dpm cm^{-2} is required for detection in 24 h. The efficiency of detection for all isotopes is enhanced if fluorography is employed (100 dpm and 500 dpm cm^{-2} for $^{14}\text{C}/^{35}\text{S}$ and ^3H , respectively).

Future Developments

PAGE, in particular 2D-PAGE, remains the method of choice for the separation of complex protein mixtures. This has necessitated the development of highly sensitive protein visualization protocols incorporating both nonradioactive and radioisotopic imaging

methodologies. The development of methods for the transfer of polypeptides from gels to membranes where they are readily accessible to react with stains, specific antibodies, group-specific ligands and detailed structural characterization, including amino acid microsequencing and mass spectral analysis, has permitted the identification of previously unidentified proteins. Further developments are likely to take place in low background staining polyacrylamide formulations and modified membrane support matrices in which proteins may be bound either covalently or which form reversible covalent bonds. Such proteins can be easily and selectively eluted for more detailed biochemical studies. Future advances are likely to take place in the development of more sensitive and group-specific dyes/stains and increased speed and sensitivity of detection systems such as the enhanced bioluminescent and chemiluminescent systems, as well as the development of faster and more sensitive photographic detection film.

Detectors for Capillary Electrophoresis

Thomas Kappes and Peter C. Hauser, University of Basel, Switzerland

Detection is a particularly critical issue in capillary electrophoresis (CE) because of the extremely small cell volumes available. Considerable effort has gone into overcoming this limitation and a bewildering

variety of methods has been described, ranging from the straightforward adaptation of existing chromatography detectors to less obvious and highly experimental techniques. The path has not been smooth, but many obstacles have turned out to be less serious than anticipated. Optical methods have proved very useful despite the short pathlengths involved. Electrochemical detection methods, intuitively considered incompatible with the applied high voltage and long neglected in favour of optical means, are now readily implemented. However, the development of detection methods is still in flux and it may take several more years before maturity is reached and different methods have found their established roles for particular applications.

The Detection Challenge

The internal diameters of the capillaries employed in CE range from 100 μm down to about 5 μm and a single analyte zone is approximately 1 mm long. Because the detection volume has to be smaller than the peak volume available, detection volumes range from about 1 pL to 1 nL. In high performance liquid chromatography (HPLC), in contrast, detection volumes of at least 1 μL are available. One would therefore expect sensitivities for CE to be several orders of magnitude lower than those in HPLC and, as a consequence, the detection limits to be much inferior. However, in CE the sample does not experience significant dilution before it reaches the detector, as is the case in HPLC, because of the flat flow profile in CE. Therefore, the sensitivities are not in fact as significantly degraded in comparison with HPLC as might be expected. Nevertheless the issue of detection limits is still critical in CE and detector sensitivity is not always adequate. Preconcentration by electrostacking is sometimes advocated, but this method is only possible for samples with low ionic strength and generally leads to poor precision unless an internal standard is employed.

Because of the small detection volumes, on-column detection schemes are required to avoid band broadening, rather than detector cells attached in an off-column arrangement as is the case in chromatography. A unique property of detection in electrophoresis, which is not shared with chromatography, is the fact that there is a dependence of the peak area (expressed on a time basis) on migration velocity. However in practice this is usually of no concern. Detection methods may be grouped according to whether a bulk property of the solution (such as conductivity, refractive index) or a specific attribute of the analytes (such as optical absorption or fluorescence, redox activity or membrane permeability) is

monitored. Detectors used in the first case tend to be more universal, but generally suffer from the presence of a large background signal against which small changes have to be distinguished. This often leads to poor signal-to-noise (S/N) ratios and hence relatively high detection limits. The exploitation of specific interactions is generally better in this regard, but each method is usually only applicable to a certain class of analytes. Some of the specific detection methods also allow additional information on the analyte to be gathered, which may be desirable as migration times can never be taken as absolute proof of identity. These detectors may be termed 'information rich', and include for example mass spectrometers, photodiode arrays and voltammetric detectors.

Important general characteristics of detectors are their sensitivity, dynamic range, and linearity. The term sensitivity generally denotes the gradient of the calibration curve but the precision of the measurement (S/N ratio) has to be considered as well for a complete evaluation. Often, the term sensitivity is used to indicate the lowest concentration that may be detected (limit of detection, LOD) and these parameters are of course interrelated. In CE detection limits are sometimes quoted in terms of the detectable mass or number of moles, as impressive figures in the pico- or atto-gram or -mole range can be given because of the small sample volumes used. However, the standard concentration limits are much more useful and meaningful. The dynamic range is encompassed by the detection limit and by a maximum where a loss of sensitivity occurs. Wide dynamic ranges are desirable as they simplify sample preparation, but they often go hand-in-hand with relatively poor precision. The upper concentration limit in capillary electrophoresis is generally determined by the ionic strength of the background buffer (typically 1–10 mmol).

The choice of detector is guided by the requirement of the application in terms of detection limit, selectivity and information requirements but to a large degree also by commercial availability, cost, robustness and ease of use. Some features of the major detection methods are summarized in Table 1.

Optical Methods

Optical detection methods are more widely employed than any other detection means. Commercial CE instruments with optical absorption detectors were introduced in 1989 and are available from a variety of instrument manufacturers. The detectors employed have often been adapted from devices used in HPLC and this may be part of the reason for the prevalence of the ultraviolet (UV) absorption detection method.

Table 1 Main detection methods for capillary electrophoresis

Method	Features	Detection limits ^a (mol L ⁻¹)
UV/Vis absorption	Readily available commercially	10 ⁻⁷
Indirect UV/Vis absorption	Compromise with poorer detection limits for nonabsorbing species such as most inorganic ions	10 ⁻⁵
Fluorescence	Good detection limits but most species require derivatization; available commercially	10 ⁻⁹
Laser fluorescence	Elaborate; excellent detection limits; available commercially	10 ⁻¹¹
Conductometry	Good for small ions; available commercially	10 ⁻⁶
Amperometry	Simple, but only possible for electroactive ions; not available commercially	10 ⁻⁸
Mass spectrometry	Provides information on peak identity; expensive; interfaces available commercially	10 ⁻⁸

^aThe values given should be considered as rough guides only, as these are often very much dependent on species and instrumental set-up. UV/Vis, ultraviolet-visible.

Fluorescence-based detectors are not as widely used but are also on the market.

To carry out on-column detection the usual polyimide protection coating has to be removed from the column by burning, by dissolution with hot sulfuric acid, or by mechanical scraping, to form a window into the capillary. The material is fairly brittle, so that care has to be taken to avoid breakage once the protective cladding has been removed. Fused silica capillaries are transparent even below 200 nm, so that the near-UV range is readily accessible.

The basic cell arrangement for absorbance measurement through a capillary is illustrated in Figure 1. Generally, besides the light source, there is a monochromator or optical filter to define the wavelength employed, a lens and aperture, and a photodetector. Variations of this arrangement are possible. Most commonly wavelengths in the UV range from about 250 nm down to 185 nm are employed, using different types of sources such as deuterium lamps, but instruments that include the visible range are also available. Variable wavelength as well as fixed wavelength arrangements are in use. It is important to get a high light intensity transmitted onto the detector for best S/N ratio. The usual UV light sources, such as deuterium lamps, are larger than the optical cell and it is only possible to focus

a small fraction of the radiation emitted through the cell even with the best available lenses. Ball lenses, mounted directly adjacent to the capillary, are often employed. Apertures are required to minimize the amount of stray light reaching the detector. Optical fibres can be used for transmission of the radiation as this allows efficient electrical shielding of the photodetector and at the same time the distal ends form the optical apertures. Absorbance detectors based on light-emitting diodes (LEDs) and laser diodes have also been demonstrated. These devices give high baseline stability because of the absence of flicker noise present in discharge lamps and allow the construction of battery operated instruments because of their low power consumption. However, these devices are not available for the UV wavelength range.

The circular cross-section of the capillary is far from ideal for absorbance measurements because it is not possible to pass collimated light through the interior of the tube without refraction. This means that changes in the refractive index of the solution are a potential source of interference. In practice, however, the only serious limitation appears to be the short optical pathlength, which leads to low sensitivity according to the Lambert-Beer law. For this reason the largest capillary diameters that allow efficient cooling are usually employed in absorbance detection, typically with an internal diameter of 50–75 μm . Different methods of increasing the sensitivity in absorbance detection have been described. These include the use of rectangular capillaries, capillaries bent in a Z-shape to obtain a longitudinal light path, multipass cells by multiple reflections in silver-coated capillaries, and so-called bubble cells formed on the capillary itself. Only the last approach is reasonably easily implemented, and it appears to be the only one that is commercially available (albeit at a cost much higher than that of ordinary capillaries).

Figure 1 Schematic representation of absorbance detector. 1, Light source; 2, monochromator or optical filter; 3, lens; 4, aperture; 5, capillary; 6, photodiode or photomultiplier tube.

The internal diameter of the capillary is widened in the detector region by a factor of about three, thereby increasing the sensitivity by the same magnitude.

A different approach to increase the sensitivity of absorption measurements is the use of thermo-optic methods. Here the heat evolved following the absorption of light is sensed indirectly. In the thermal lens method the refraction of a laser light beam is measured, using a relatively simple arrangement. Two light beams perpendicular to each other are employed. One of the beams is of a wavelength that is absorbed by the analytes. The heat evolved through absorption of light leads to a refractive index gradient in the capillary which is monitored by the second beam. A variation on this technique has been reported that uses intensity-modulated light. This leads to a vibration of the capillary that may again be detected with a second probe beam. Ordinary refractive index detection has also been described using the deflection of a laser beam but neither of these two techniques has gained much acceptance.

Most organic analytes possess chromophoric groups that show intrinsic absorbance in the near-UV range, so most methods are based on this wavelength region. It has been demonstrated that for these species it is preferable to use wavelengths that are as short as possible (below 200 nm) for the best sensitivity. Photodiode-array detection is also possible. This technique yields additional qualitative information on the identity of the detected species and allows peak inhomogeneity to be detected. However, the S/N ratio and therefore the detection limit, which is always critical in CE, are degraded because of the reduced integration time available, and the method requires considerable computing power, because of the large amount of data acquired. Ions that do not show absorbance in the UV/Vis range, such as inorganic species or completely saturated organics, may be determined by indirect methods. These methods rely on the displacement of dye molecules of equal charge as the analyte species (to maintain electroneutrality) so that a decrease in absorbance is detected. This is more demanding on the stability of the system than the direct absorbance method and the detection limits are generally higher. However it is the only method employing optical absorbance detectors to be available for most inorganic anions. Chromate is often used as the background ion but other species, some for the visible wavelength range, have also been reported. Inorganic cations can also be detected by indirect means, but many of them are best determined via the formation of coloured complexes using non-discriminating ligands.

Fluorescence detection is also possible and is commercially available. However, few species display in-

trinsic fluorescence, so derivatization reactions have to be employed. Derivatization may be classified as pre-column, on-column or post-column according to the scheme employed. Fluorescence has the great advantage of much higher sensitivity than absorbance measurements. Detection limits approaching single molecule detection have been achieved. Lasers appear to be ideal light sources for fluorescence measurements, as the light is produced in a tightly focused beam well matched to capillaries, but inexpensive sources are not available for the UV range and available lasers are often plagued by insufficiently stable output intensities. This limits their use, especially for the more universal indirect detection scheme. Nevertheless, impressive results have been obtained for microbiological applications (e.g. in neuroscience) that include the analysis of single cells. Chemiluminescence detection is usually based on the influence of analytes on the efficiency of one of several available chemiluminescence reactions. The achievable sensitivities are very high, a feature this method has in common with fluorescence. Its implementation is similar to post-column fluorescence detection in that a pumped reagent stream has to be merged with the column effluent in a suitable small-scale mixing device prior to detection in a light-tight enclosure with a photomultiplier tube.

Electrochemical Methods

Electrochemical detection techniques in general are developing rather more slowly than optical techniques, even though some of the earliest examples of open tubular electrophoresis were based on electrochemical detection. It was considered that the electrical field applied for separation was a serious hindrance. Also, the exposure of the detector to the buffer solution (which is not the case for the optical methods) is a potential source of problems as the electrodes may corrode or be affected in other ways. While the common optical detection methods have reached maturity, the same cannot be said for the electrochemical methods. Of the three reported methods, namely conductimetry, amperometry and potentiometry, the former is the only one that is commercially available at this time. Nevertheless, these methods have attracted considerable attention and in general are much simpler than other methods.

In an early approach to conductivity detection, the cell was formed by drilling a hole perpendicularly through the capillary with a laser and then inserting two small wires that faced each other. In this way the two detector electrodes were not exposed to a voltage gradient. Another approach, which is still used by some workers for amperometric detection, is to

Figure 2 Common arrangements for electrochemical detection. (A) Decoupled configuration with on-column detection using a micro-electrode. (B) Wall-jet arrangement possible with capillaries with internal diameters of 50 μm or less, showing a relatively large electrode at a suitable distance from the capillary end.

decouple the detector from the electrical field. This is achieved by creating a small gap in the capillary and using a sleeve typically made of an ion exchange membrane to provide a contact to the electrical earth. This arrangement is illustrated in Figure 2A. The analytes are pushed forward to the detector electrode(s) by the pressure created by the electroosmotic flow. This arrangement is ideal in an electrical sense but cumbersome to implement. However, it was later realized that if electrodes are positioned immediately outside the end of capillaries that have internal diameters of 50 μm or less, then the electrical bias on the detector is minimal. This arises because the cross-section of the liquid volume outside the capillary is considerably larger than that inside, so that the remaining voltage drop between the end of the capillary and the electrophoretic earth electrode located a few millimetres away is a few hundred millivolts only. Inside the capillary voltage drops of 30 V mm^{-1} are typically encountered. Also, the electrical current through the capillaries is considerably lower for smaller internal diameters. This so-called wall-jet arrangement (Figure 2B) is the one used in commercial instruments for conductivity detection, and this same configuration is also frequently employed for the other two electrochemical detection methods. A further feature of the wall-jet configuration is the use of electrodes with diameters larger than the internal diameter of the capillary, which was found to be possible without significant loss of peak resolution.

This allows the construction of relatively simple cells for the alignment of capillary ends and electrodes.

In conductimetric detection it is essentially the same property which is responsible for the separation, namely the mobility in the electrical field giving rise to a detector signal. This means that in principle any species that can be separated by CE may be detected by conductimetry. However, the need for an electrolyte in the running buffer leads to the presence of a background signal against which the analyte signal has to be measured. As the analyte displaces ions of the same charge (the same feature exploited in indirect absorbance detection), it is the difference in conductivity (caused by a difference in mobility between background and analyte ions) that leads to a detectable signal. To optimize the sensitivity the conductivity of the background buffer should be low, a requirement that conflicts with the need for matching the mobility of the buffer to that of the analytes to prevent peak tailing or fronting. A compromise therefore has to be made. For analytes with low conductivity indirect detection may be employed using a background electrolyte with high conductivity.

Conductivity detection can also be carried out in a contactless configuration with two tubular electrodes placed over the capillary. These then form capacitors (albeit with small capacitance values) with the liquid, whose conductivity can be probed with an applied high frequency alternating current. Electrode degradation is prevented in this mode. The sensitivity of conductivity detection can be improved by the so-called suppressed detection technique, known from ion chromatography, in which the background conductivity is largely removed by using a weak acid or base that is rendered neutral by ion exchange before the detection cell. However, for CE an arrangement similar to that used for electrical decoupling is required for suppression. This is difficult to implement and the method has not found wide use.

Amperometric detection may be employed for ions that are electroactive, i.e. that can be reduced or oxidized at electrodes. Different classes of species show this property, including heavy metal ions, certain inorganic anions, and many different organic molecules that incorporate reactive groups such as phenols, aldehydes, amines, etc. Many applications of amperometric detection have been reported but these have certainly not been fully explored yet. As the detection limits of amperometry tend to be good this approach is useful when low concentrations are to be determined. Please note that the terms 'electrochemical detection' and 'EC detection' are often employed with the sole connotation of amperometric detection, a usage that has evolved in the context of HPLC detection methods. This may lead to confusion as

conductimetry and potentiometry clearly are electrochemical methods as well.

At this stage detector cells for amperometry have to be constructed in-house as (at least to our knowledge) no commercial units are available. However, all the other parts required to set up a CE instrument, including potentiostats to operate the detector, are available commercially in modular form. In the wall-jet arrangement, the voltage applied to the working electrode by the potentiostat circuitry is superimposed by a voltage bias that is not only dependent on the applied separation voltage but also on parameters such as buffer composition, capillary diameter and the exact position of the electrode. For this reason some workers continue to use the decoupled detector. Amperometric detection in CE in principle requires a total of four electrodes at the detector end of the column. Besides the detector electrode (the working electrode of the potentiostat circuitry) and the electrophoretic earth, a reference electrode and a counter (or auxiliary) electrode are required. It is possible to simplify this configuration by employing the electrophoretic earth as a pseudo-reference and as a counter electrode as well.

Different electrode materials may be used in amperometric detection including gold, platinum and glassy carbon to suit different applications. The use of copper wire electrodes has proved to be useful as several oxidation reactions are catalysed on this material. Pulsed amperometric detection (PAD) may be employed when reaction products lead to a fouling of the electrode. Voltammetric detection in which the applied electrode potential is swept rapidly and repeatedly over the range of interest to gain additional information on the peak identity via the redox potential is also possible. Somewhat higher detection limits may have to be accepted, however, for these pulsed methods.

Potentiometric detection with ion selective electrodes is the least reported of the three electrochemical detection methods. The matching of a separation method with a sensor (rather than a detector which by definition is not selective) may appear to be a contradiction, but ion selective electrodes are in fact rarely highly selective and may be tailored to be responsive to a range of ions. So-called Hofmeister electrodes discriminate solely on the basis of the lipophilicity of the anions or cations, and are therefore at least in principle well suited for the determination of singly charged organic species. Early reports on this technique were based on micropipette ion selective electrodes known from physiological studies on single cells. These electrodes consisted of glass capillaries, with tip diameters of a few micrometres, that were filled with a viscous organic solvent incorporating an ionophore and acted as ion selective membranes.

However, these electrodes were not very robust and have now been superseded by more reliable miniature coated-wire ion selective electrodes. These detectors have been used to detect a variety of inorganic and organic species that otherwise could not be detected with CE, or could only be detected with difficulty. It is possible to use a copper wire electrode as a simple potentiometric detector for amino acids in CE.

In summary, the three electrochemical methods may be considered to be complementary. Conductivity detection is a versatile general method that works best for small ions of high mobility. Amperometric detection is useful for electroactive ions and good detection limits can be expected. Potentiometric detection has currently been relatively poorly explored, but may prove to be a useful alternative for large, singly charged ions that cannot be detected amperometrically or by direct optical absorption measurements.

Other Methods

Detection methods other than optical or electrochemical methods have also been reported. One method that is fairly widely used is mass spectrometric detection, including detection by inductively-coupled plasma mass spectrometry, and commercial interfaces are available. Detection by nuclear magnetic resonance is also an established technique. These methods are covered elsewhere in this encyclopedia. Radioisotope detection has been reported and good detection limits have been achieved.

Future Developments

The acceptance of CE depends to a large extent on the availability of suitable robust detection methods with good detection limits. Shortcomings appear to exist for trace analysis of organic species that do not fluoresce, and for inorganic species. Thermooptic and chemiluminescence methods are promising in this regard as are the electrochemical methods of amperometry and conductivity. The last two methods appear to have reached some degree of maturity and it is hoped that these will become more readily available commercially.

Introduction

Electrophoresis is one of the most powerful tools in the arsenal of separation scientists. It is commonly employed in the field of biochemistry, where separation of complex mixtures of proteins or nucleic acids is a continuing challenge. Numerous variants of electrophoresis have been described with the goal of optimizing the speed and effectiveness of the separations. One important electrophoretic variable is the separation matrix. It provides the retarding forces, or sieving qualities, that counter the electrophoretic transport. These forces can ultimately effect the separation and can be altered by the matrix type or concentration. Cross-linked or linear forms of polymers such as agarose or acrylamide are common choices. Different formats for the electrophoresis medium can also have dramatic effects on the resolution and separation time. This is exemplified by recent uses of microcapillary formats which greatly speed up separations. Another component that dictates the speed and resolution of electrophoretic separations is the charge-carrying buffer ion. The buffer is a universal component of electrophoresis, independent of gel constitution or format. This component is often overlooked, though attention to this aspect can be beneficial in developing electrophoresis-based separation techniques.

Proper buffer selection offers several practical advantages, including optimum separation times, in-

creased band concentration and reduced effects of diffusion. The resolution of closely migrating species results from the proper choice of the pH, concentration, and type of buffer ion. These physical characteristics define the conductivity of the electrophoretic medium and affect the transport of the molecules to be separated. Inorganic ions, such as chloride anion, have high conductivities in comparison to the ionized form of weak acids and bases. Such high mobility ions offer little advantage when used for the electrophoretic separation of large, less mobile biomolecules but slower-moving ions, such as those of weak acids or weak bases, are more useful choices. These not only buffer the pH but, due to the slower mobility of these ions, lead to better separation of charged macromolecules.

Zonal electrophoresis utilizes a single buffer in the gel and reservoirs. An alternative to the continuous buffer, zonal separations is a discontinuous system where multiple ionic components are used. The presence of multiple ionic components in electrophoresis leads to discontinuities in the voltage gradient, pH and ionic strength due to the different physical mobilities of the ions involved. These different mobilities lead to the formation of discrete zones of ions that, under equilibrium conditions, travel at a constant rate in an applied electric field. Adjustment of these mobilities involves alteration of the ion concentration and potential gradient of the zone. Sharp boundaries can exist between these zones, with the ionic concentration being dictated by the Kohlrausch regulating function. The technique is similar or identical to a number of electrophoresis techniques that are known as discontinuous multiphasic, multizonal,

displacement, isotachopheresis and moving boundary electrophoresis. The primary advantages of discontinuous buffer systems over continuous buffer, zonal separation are their ability to concentrate dilute samples, enhance resolution between closely migrating species and provide defined reference fronts.

Implementation

Most of the electrophoretic techniques that exploit the differential migration of ions in an electric field trace their origins to the work of Kohlrausch. In 1897, Kohlrausch presented the equations that describe ionic migration in an electric field. In later decades, Tiselius furthered electrophoretic techniques and accomplished the separation of serum proteins using moving boundary electrophoresis. In 1958, Poulik published the use of the discontinuous buffer technique for the separation of proteins in a starch gel and, a few years later, Ornstein and Davis described the theory of discontinuous buffer systems for the separation of serum proteins in polyacrylamide gels. The Ornstein and Davis 'disc' electrophoresis system concentrated the sample by placing it between buffers of different mobility and then performed the separation using zone electrophoresis. In 1965, Richards applied the technique for the separation of nucleic acids. Since this period, discontinuous buffer systems, or similar techniques, have seen consistent usage in protein separations. Theoretical treatments that aid in the design of appropriate buffer systems have been extended. This has led to the description of various buffer systems for the separation of both acidic and basic proteins and the development of 'spacer' ions for resolving closely migrating proteins. The application to nucleic acid separations has been sporadic. This is perhaps due to the lower reliance on charge differences for the separation of nucleic acids. In

contrast to proteins, nucleic acids have a near constant mass-to-charge ratio giving them a common free electrophoretic mobility. Typically, zonal gel systems that fractionate solely on size are used. However, discontinuous buffer systems do offer advantages for certain nucleic acid separations.

In practice, a leading ion is chosen such that the mobility of this ion is greater than all others in the system. This ion is incorporated into the separation matrix (or in some applications, an anti-convective matrix). The trailing ion(s), with a mobility slower than the leading ion, is placed in the top buffer reservoir while a counterion, common to all zones, is placed in the bottom buffer reservoir. For open-faced gel systems, the samples are loaded directly on to the separation matrix, while for vertical slab systems the sample can be loaded on top of the gel. As the moving boundary is established, the sample will be concentrated in a very thin moving boundary. The analytes to be separated will stack themselves in the order of their ionic mobility and, in the case of discontinuous electrophoresis, may be further fractionated by the use of a sieving gel. The resultant bands are easily detected with conventional techniques, using stains or fluorescent or radioactive labels. A description of a typical experimental set-up, and the identity of the various ionic species for an anionic separation, is shown in Figure 1.

Only the concentration of the leading ion can be chosen freely. During electrophoresis, the ionic concentration and potential gradient of the trailing zones will be regulated to compensate for the lower mobility. This regulating function is known as the Kohlrausch regulating function. Under equilibrium conditions, the leading and trailing ions migrate at the same rate (isotachopheresis). This causes the ion concentration in a trailing zone to be lower, and the voltage gradient to be higher, than that in a leading

Figure 1 Pictorial description of the progress of an electrophoretic separation using a discontinuous buffer system. The initial set-up is shown on the left. A trailing anion, B^- , is placed in the cathodal buffer reservoir while the leading ion, A^- , is placed in the gel. This leading anion has a mobility that is greater than all other anions in the system. A common counterion, C^+ , is used throughout the reservoirs and gel. The centre panel shows the sample being concentrated by the moving boundary created by the dissimilar anions. As this boundary traverses through the gel, the sample components, with mobilities that are slower than the trailing anion, will be fractionated in the trailing zone. Those ions with an intermediate mobility will be retained in the moving boundary. This is shown on the right.

zone. These differences compensate for the lower free mobility. The migration rate of the ions can be followed by observing the position of the boundary between the zones. This boundary is self-sharpening, as 'trailing ions', if present in the leading zone, will be in a low field region and slow down, while 'leading ions' in the trailing zone will be in a high field region and speed up. This boundary can be conveniently demarcated by incorporation of a low concentration of a dye with a mobility intermediate between the leading and trailing zone. Alternatively, conductivity or thermal changes can be monitored to detect the passing of the boundary. Multiple boundaries can exist with each one defining a distinct zone. Since the concentration of ions in the zone is regulated, the size of the zone will depend on the quantity of material and the concentration of the leading ion. Thus, dilute samples can be concentrated and different ions can be sorted based on their mobilities.

Selection of appropriate buffer systems usually requires some knowledge of the charge and mobility of the analytes to be separated. Many buffer systems, which span the entire range of pH values, have been described. These systems are especially useful for the separation of proteins that are charged under specific pH values. The mobilities of the charged analytes to be separated are also critical. For molecules that are subsequently to be fractionated within the trailing zone, the trailing ion should have a mobility that is similar to or intermediate between the ions to be separated. Tuning the mobility of the trailing ion to that of the analyte can minimize the conductance changes across the sample. This can lead to sharp band profiles and enhance the resolution of closely migrating species. Reference to previously tabulated buffer mobilities will aid in the selection of an appropriate buffer system. The development of new buffer systems can be accomplished empirically or through simple application of the equations describing discontinuous electrophoresis.

Advantages

The primary advantage of discontinuous buffer systems is the ability to concentrate the sample zone. The passage of the moving boundary has the effect of sweeping the sample into an extremely thin starting band. For analytical applications this can lead to reduced band widths and higher resolution separations. This feature has obvious advantages for the characterization of closely migrating species. For preparative applications, the result is the concentration of dilute samples. Another advantage of discontinuous buffer systems is their use as an analytical tool for defining relative mobilities. The mobility of

the ion front is easily defined and can serve as a reference for defining relative mobilities. Furthermore, the mobility of the front is reproducible and independent of the gel matrix. These features can be convenient for analytical and forensic applications. Additionally, the mobility of sample ions can be altered by changing the mobility of ions in the trailing zone. This can lead to the tailoring of separations by defining the size range that can be fractionated. Sample ions that are not of interest can remain trapped in an ion front, allowing examination of particular ions. Finally, discontinuous buffer systems are compatible with virtually any gel format, as its use is independent of the gel matrix or the physical format of the gel. Since it alters only the buffer system, the only complication is selecting an effective buffer. Fortunately, the characteristics of many buffer systems have been described and designing new systems is a straightforward task, as described below.

Figure 2 exemplifies some of the features of discontinuous buffer systems for nucleic acid separations. Shown here is a portion of a DNA sequencing gel using a denaturing formate-glycine discontinuous buffer system. An intermediate zone, with a mobility between the formate leading ion and the glycine trailing ion, was inadvertently created from contaminating ions in the gel or sample loading buffer. For analytical application, care should be taken to ensure that extraneous ions are absent. However, the presence of this ion species demonstrates the effects of stacking limits on the size selection and band concentration of DNA sequencing products. DNA bands smaller than 106 bases are trapped in the first ion front while DNA sizes 115–166 are trapped in the second front. The DNA sizes that are trapped in the ion fronts define the stacking limits and cannot be separated because their mobility is between that of the migrating ion zones. Since the DNA is not freely electrophoresing, these stacking limits could be altered by changes to the gel matrix. The intermediate ion zone demonstrates other features. Its size is directly proportional to the amount of contaminating ion that is present. Larger amounts of contaminating ion would expand this zone. Additionally, the eight DNA bands in this zone are much sharper than the bands migrating behind the second front, even after the 30 cm migration distance. This is due to the concentrating effects of the leading ion front and the closely matched mobility between these DNA bands and the ions in the zone.

Theoretical Description

Calculation of the ion concentrations and basic characteristics of the leading and trailing ion zones are

Figure 2 The differential effects of stacking limits on the migration of DNA sequencing products on a 6% polyacrylamide gel (containing 5% bis-acrylamide cross-linker) with a 50 mmol L⁻¹, pH 9.0 formate leading ion, glycine trailing ion. The sequence between the two fronts, AAATTGTT, corresponds to fragment lengths of 107–114 bases; the sequence behind the front, CTGG, corresponds to fragment lengths of 167–170 bases. Fragment lengths between 115 and 166 bases are concentrated in the second front while fragment lengths < 107 bases are concentrated in the first front.

easily accomplished through use of a few simple equations. The starting point is the Kohlrausch regulating function (R) that describes the moving boundary condition:

$$\sum \frac{C}{m} = R_n \quad [1]$$

where C is the concentration of the ion in zone n and m is the mobility of the ion. These values are signed according to the charge of the ion. For the set-up described in Figure 1, the regulating functions characterizing the two zones would be equal under moving boundary conditions and:

$$\frac{C_1^{A-}}{m_{A-}} + \frac{C_1^{C+}}{m_{C+}} = \frac{C_2^{B-}}{m_{B-}} + \frac{C_2^{C+}}{m_{C+}} \quad [2]$$

where the concentration subscripts denote the zone. This relationship, along with the condition for

electroneutrality:

$$C_1^{A-} + C_1^{C+} = 0 = C_2^{B-} + C_2^{C+} \quad [3]$$

allows definition of the basic relationship between the concentration of ions in the different zones and their mobilities:

$$\frac{C_1^{A-}}{C_2^{B-}} = \frac{m_{A-}(m_{B-} - m_{C+})}{m_{B-}(m_{A-} - m_{C+})} \quad [4]$$

This relationship can be defined for every boundary in a discontinuous electrophoresis system. The relationship is valid for strong electrolytes and weak electrolytes. For weak electrolytes, the concentration value represents the total of the ionized and un-ionized forms. The fraction of the trailing species that is ionized, $X(n)$, can be determined after calculation of the amount of counterion that crosses the boundary into the trailing zone. When using a weak electrolyte as the counterion, a final expression for the counterion concentration in the trailing zone is:

$$C_2^{C+} = C_1^{C+} + C_1^{A-} \left(\frac{m_{C+}}{m_{A-}} \left(1 - \frac{(m_{A-} + m_{C+})}{(m_{C+} + m_{B-})} \right) \right) \quad [5]$$

where the counterion concentrations are the total concentration (both ionized and un-ionized forms). The fraction ionized, $X(n)$, can then be calculated from the ion equilibrium constants of the trailing ion and counterion. The net mobility accounts for the actual transport of the trailing acid species and is defined as:

$$\text{net mobility}(n) = m_n X[n] \quad [6]$$

The net mobility should be tuned closely to the sample's mobility. Sample mobilities faster than the trailing ion net mobility will be retained in the ion front. Details regarding these equations and more rigorous definitions can be found in numerous references.

A few characteristics of discontinuous buffer systems are apparent from examining the above equations. First, the equilibrium concentration of the trailing ion is independent of its initial concentration. It is determined by the free mobilities of the ions in the system and the concentration of the leading ion. Therefore, only the leading ion conditions can be chosen freely. Second, since the trailing ion has a slower mobility than that of the leading ion, the concentration of the trailing ion must be lower than that of the leading ion. This bears directly on the conductance and potential gradient of the trailing

zone. The zone conductance, κ , can be calculated from the ion concentrations, free mobilities and Faraday's constant (F). It can also be related to the field strength (volts (V) per unit length (l)) through Ohm's law, as shown (where i is the current and A the cross-sectional area of the gel):

$$\kappa = F [(\text{net mobility}(B^-))(C_2^{B^-}) + (\text{net mobility}(C^+))(C_2^{C^+})] = \frac{i}{A(V/l)} \quad [7]$$

Since the ion concentrations and ion mobilities in the trailing zone are lower than that in the preceding zone, the potential gradient in a trailing zone will be higher than the leading zone. This is what allows the trailing ions to migrate at the same rate as the leading ions, despite their lower physical mobility. Tuning the ionic strength is critical for optimizing separations. It affects the size of the migrating zone, the speed of the separation and the joule heating. The joule heating further influences resolution. Therefore, a high potential gradient for a given current, or heat output, will be preferable.

The above equations can be implemented on simple spreadsheet software to determine the physical characteristics of discontinuous buffer systems. A few example buffer systems are shown in Table 1. These buffer systems have been designed to vary the trailing ion type and the trailing ion net mobility while keeping the ion speed constant. A Tris-formate buffer, at a formate concentration of 50 mmol L⁻¹, has been selected as a common leading ion. Tris is used as a common counterion. The ion speed and voltage gradient would be determined by the applied current. These buffer systems exemplify some of the characteristics of discontinuous buffer systems. As can be seen, the trailing ion concentration is lower than the leading ion concentration and a wide range of net mobilities can be achieved when using a common

leading ion. Also notice that the net mobility, or actual transport of the trailing ion, is lower than the free mobility when using weak electrolytes. Such buffer systems can be used to assess the stacking limits, or mobility, of the analytes to be separated. Sample ions that migrate in the ion front will have a mobility intermediate between the leading and trailing ions. Those sample ions that have a mobility slower than the net mobility of the trailing ion will migrate more slowly than the ion front and will electrophorese within the trailing zone.

Other examples of calculated buffer systems are shown in Table 2. These buffer systems vary the trailing ion type while keeping the ionic strength of the trailing phase constant. This is accomplished by varying the leading ion concentration to allow for a predetermined ion concentration in the trailing zone. All the buffer systems in Table 2 use a formate leading ion of varying concentration and have a common trailing ion concentration of 30 mmol L⁻¹. Even with a common trailing ion concentration, a 50% change in the conductance can be obtained. This allows for increased voltages to be applied without increasing the current. As with the buffer systems described in Table 1, a range of trailing ion net mobilities is obtained. Other buffer systems, that define different ranges of net mobilities, different pH values or different conductivities, could be similarly calculated to address particular separation problems or analytical characterizations.

Outlook

Electrophoretic techniques that exploit the differential migration of ions are over 100 years old. Though the applications and physical formats have evolved, the underlying technique continues to endure. The iteration of discontinuous buffer systems has had intermittent use since its introduction over 30 years ago. This is presumably due to the perceived added

^aThe leading ion in all cases is formate (ion mobility of 5.50×10^{-4} cm² V⁻¹ s⁻¹) at the indicated ion concentration. The counterion in all cases is Tris (ion mobility of 2.60×10^{-4} cm² V⁻¹ s⁻¹).

complexity of the technique or ignorance of the technique's advantages. However, the benefits of sample stacking, mobility tailoring and an ionic reference front are unchanged and unique when compared to zonal buffer systems. With new applications and challenges for electrophoretic separations, renewed attention to the technique is certain.

Introduction

The application of electric fields to planar chromatographic media in order to drive and/or enhance separations is as old as planar chromatography itself. There is evidence to suggest that paper electrophoresis was first performed several years prior to the first

reports of paper chromatography. Research in the field has been intermittent, with periods of considerable activity separated by long periods of inactivity. This is at least partly due to attention being diverted away from planar methods to modern high-efficiency column techniques. It is quite conceivable that modern chromatography would be very different, with a much stronger focus on planar techniques, had more development work been carried out on thin layer electrochromatography (TLE).

The subject is enjoying something of a revival with significant advances having been made during the

1990s. If this trend continues, planar electrochromatography may take its place as a powerful tool in the modern analytical laboratory offering new modes of separation at speeds that are currently unavailable in conventional thin-layer chromatography (TLC).

Definitions

The term TLE will be used to refer to all techniques carried out within chromatographically active thin layers and with electric fields being employed to influence the separation. This will encompass a number of different modes of separation, including those that are dominated by electrophoretic analyte migration but which, due to the nature of the layer, include some element of chromatographic retention. Conventional gel-based electrophoresis is therefore distinguished from TLE by the electrophoresis in TLE being carried out in a chromatographically active layer of material such as silica, alumina or cellulose. TLE therefore excludes gel electrophoresis carried out in cast gel slabs of materials such as polyacrylamide that are commonly used for the separation of proteins and DNA. Paper electrophoresis is now largely obsolete and is not therefore covered.

Advantages of TLE

Thin-layer chromatography has proved to be one of the most successful chromatographic techniques ever devised. This success owes largely to its simplicity and versatility compared with column techniques. The main drawback of TLC is the low solvent velocity achieved through capillary action. This leads to long separation times and means that the optimum flow velocity (for chromatographic efficiency) is seldom reached. Electric fields can be used to cause the migration of the analyte, either by directly exerting a force on the molecules, or by causing the eluting solvent to flow, carrying with it the analyte. This can result in migration velocities of one to three orders of magnitude greater than those achieved through capillary action and can introduce an electrophoretic component to a separation, facilitating the separation of difficult mixtures.

Electrophoresis

This is the migration of ionized species under the influence of an electric field. Ions in an electric field experience a force proportional to their charge, causing them to accelerate in the direction of the field. Ions in solution, not interacting with a solid support, reach a terminal velocity dependent on the magnitude of the force and their interaction with the solvent. Therefore, different ions will migrate through the

solvent at different rates. This can be used to separate different ions and is known as free solution electrophoresis.

If the solvent is within a bed of chromatographically active media such as silica, the migrating ions can interact with the solid support, adding a chromatographic component to the separation. At this point, it is simpler to refer to the separation as electrochromatography, which encompasses both electrophoretic and chromatographic effects.

The ionic mobility u can be expressed in terms of the ion's velocity v in a given electric field strength E by $u = v/E$. This only applies to free solutions, since migration through the channels of a solid support follows a tortuous path that deviates from a straight line by a quantity dependent upon the properties of the solid support. The important point is that the migration velocity, both in free solution and through a bed of chromatographic media, is proportional to the potential applied. In order to achieve greater migration velocities, it is necessary to apply higher potentials.

Electroosmosis

Electroosmotic flow arises from the formation of an electrical double layer at a solid-liquid interface. This is due to the presence of charged species on the solid surface; either in the form of surface ionized groups (e.g. SiO^- in the case of silica) or because of the preferential adsorption of ions from the solution. In most cases it is a combination of both. The surface charges are counterbalanced by ions in solution, which form an immobile, strongly bound layer near the surface and a mobile, solvated layer extending into the liquid. Under the influence of an applied potential, the solvated layer of counterions moves, causing bulk solvent flow (Figure 1).

This means of inducing solvent flow has been successfully applied to capillary column chromatography, producing capillary electrochromatography (CEC). Using electroosmotic flow (EOF) to pump solvent through a column generates a 'plug' flow profile, which is distinct from the parabolic profile generated by hydraulic pumping. This results in reduced band broadening in CEC. It also allows the use of very fine chromatographic supports, which would be impossible to use in pressure-driven systems owing to back-pressure constraints. These factors combine to give high linear flow rates, of the order of 1 mm s^{-1} , allowing very fast, efficient separations.

As with electrophoretic migration, the EOF velocity increases linearly with applied potential. This makes it generally desirable to apply higher potentials in order to achieve faster migration rates.

Figure 1 A schematic representation of double layer formation at a silica surface.

Modes of Migration

In standard TLC, the migration of a sample molecule is controlled by its interaction with the bed of chromatographic media and the partition of the solute into the eluting solvent. In electrically driven TLC, the solutes may be made to move in a number of different ways.

If the sample molecules are ionic in the solvent used, the application of an electric field will exert a force on them and they will migrate electrophoretically. As they migrate they are also subject to chromatographic partitioning between the solvent and the stationary phase. The individual components separate from each other by migrating at different velocities, each compound having a characteristic migration velocity that reflects the conflict between electrophoretic migration and chromatographic retention.

If, however, the sample molecules are uncharged in the solvent, they will only migrate if the solvent is made to flow. Whereas in standard TLC this is achieved by capillary action, in electrically driven TLC, with the right solvent and adsorbent, it can be achieved through EOF. The separation that results from an electroosmotically driven TLE experiment is, in the absence of electrophoretic effects, similar to that obtained by conventional TLC, but it is obtained much more rapidly.

There is a third mode by which solvent flow can be induced through a thin layer chromatographic media during an electrochromatography experiment. When a current flows through a wetted layer of chromatographic material the layer heats up. The power which has to be dissipated from the plate depends on the current flow and hence the resistance of the wetted plate. When the solvent is unevenly distributed through the plate this leads to an uneven evaporation

of solvent from the plate causing capillary solvent migration to occur as a direct result of Joule heating. This effect is more extreme with vertically mounted plates, which under gravity drain solvent to the base of the plate. In some experiments, evaporative flow can be considerably larger than that which is generated by electroosmosis. This can be falsely identified as EOF and is particularly evident in experiments carried out with vertically mounted plates. In horizontally mounted plates, with a solvent reservoir at each end of the plate, solvent is replenished least quickly at the center of the plate. If the rate of evaporation is initially assumed to be uniform across the plate, then the middle of the plate will dry out more quickly. This leads to solvent flow from both ends of the plate towards the middle being superimposed upon any EOF.

The current flow through the solvent-wetted chromatographic layer is dependent on the overall electrical resistance of the plate, which is a function of the ionic density in the solvent. These ions may originate from soluble ionic species in the chromatographic material, dissolved ions in the solvent or dissociated solvent molecules. The smaller the ionic density, the higher the overall plate resistance and the smaller the current. Unless adequate cooling is provided, the input of power will cause a temperature rise in the thin layer. This will lead to evaporation of the solvent, the rate of which will depend upon the rate of power influx, the volatility of the solvent and degree of external cooling. This is the main limitation controlling the magnitude of the potential that can be employed in TLE to achieve faster migration rates.

Various methods of cooling the plates have been used in order to reduce solvent evaporation. Immersion of the plate in a solvent that is immiscible with the eluting solvent has been employed in various separations, with CCl_4 being the most popular coolant for aqueous eluent systems. The purpose of the solvent bath is to provide direct cooling to the plate surface. This approach was experimentally clumsy and limited the range of analytes, since analyte solubility in the 'coolant' must be considered. It was later dropped in favour of the use of cooling pads in contact with the TLE plate, achieving cooling rates in excess of 0.1 W cm^{-2} . With high-conductivity aqueous systems this arrangement allowed the applied potential to be raised to 160 V cm^{-1} , generating migration velocities of up to 0.1 mm s^{-1} .

Solvents with limited volatility, such as higher alcohols, propylene carbonate and formamides have been used to reduce evaporation. This approach did not however gain popularity owing to several experimental limitations, the most important of which is the difficulty in removing the eluting solvent from the

chromatographic material following an experimental run. This is usually necessary in order to visualize the separated compounds.

Historical Development

The development of TLE occurred in tandem with that of paper electrophoresis (Table 1). This is not surprising, since both techniques require similar apparatus and reagents, and are generally used to achieve the same types of separation. TLE has always had an advantage over the paper technique in terms of chromatographic performance. The finer and more uniform surface structure achievable on thin layers results in considerably reduced band broadening when compared with fibrous media.

The earliest experiments were carried out in the 1940s using paper and layers of silica gel. A wide range of analytes was separated, largely employing aqueous systems. The high conductivity of the aqueous systems limited the applied potential to 10–50 V cm⁻¹ but the electrophoretic separations achieved at these potentials were still a considerable improvement on those obtained by the equivalent paper chromatography/TLC separations. The run times were typically of the order of 1–3 h, but some experiments, particularly protein separations, were run for as long as 24 h.

The development of gas chromatography (GC) and high-pressure liquid chromatography (HPLC)

enabled high-efficiency separations to be achieved and diverted attention away from planar techniques. This led to thin-layer electrophoresis/electrochromatography being largely abandoned in the late 1960s in favour of the column techniques. Very few publications between 1970 and 1998 cite the use of TLE.

Following a period of active research into planar techniques between 1940 and 1960, interest in TLE has been sporadic at best. Long periods of inactivity have been punctuated by occasional reports of technical advances and/or applications of the technique. Possibly one of the most important of these is a paper by Pretorius *et al.*, which described very high-speed separations both on TLC plates and in columns utilizing EOF to mobilize solvent. This paper set a precedent, by using nonaqueous and low aqueous solvents, potential gradients of around 1000 V cm⁻¹ could be used – potentials at least five times greater than had been previously employed. The experiments carried out in columns were quickly followed up by several other research groups and are considered the direct predecessor of modern capillary electrophoresis (CE) and CEC.

Experimental Techniques

Development Chambers

Historically, the majority of TLE experiments have been carried out in the horizontal mode, with solvent reservoirs at both ends of the plate. This set-up continues to be used today by several groups, and is shown in Figure 2. The plates are supported with the chromatographic surface either up or down.

Solvent is transported to and from the plates by wicks, which also serve as electrical contacts. A range of materials has been used as wicks, including filter paper, sintered glass and felt. The electrodes are usually submerged in the solvent and made of an inert conductive material, such as silver, stainless steel, carbon or platinum.

A less popular approach involves the use of vertical plates, with solvent at the base of the plate (Figure 3). Electrical contact is made via the solvent at the base

Table 1 Developments in thin-layer electrochromatography

1937	Earliest recorded use of paper electrophoresis, separation of snake venom proteins followed by UV detection (Konig)

and an electrode fixed at the top of the plate. While in such systems the solvent is sometimes described as migrating up the plate because of electroosmosis, this may not always be strictly true. The main limitation of this arrangement stems from the lack of solvent reservoir at the top of the plate, and uneven solvent evaporation from the plate can impart a capillary-driven component to the solvent migration. This makes it difficult to differentiate between electroosmotic solvent flow and capillary solvent flow. Some workers have placed a second solvent reservoir at the top of the plate, and generated electroosmosis in a downward direction.

Chambers are usually sealed from the atmosphere in order to provide a solvent-saturated atmosphere, thus reducing evaporation. Some arrangements employ a cover plate, usually glass, in direct contact with the chromatographic surface in order to minimize evaporative effects.

Plates

A wide range of stationary phases, mobile phases and operating conditions have been employed in TLE. The layer is frequently 50–200 μm thick on a backing material of glass or organic polymer. Aluminium-backed plates are not suitable for use in TLE because of their electrical conductivity. TLE has been carried out on all thin layer adsorbents used for TLC, with silica, microcrystalline cellulose and alumina attracting the greatest interest.

Plates are generally 10–20 cm long and 5–20 cm wide. Longer plates tend to suffer from evaporative flow more than short ones and are generally avoided. The width of the plate is limited only by the current that the power supply is able to deliver at the required potential.

Solvent Systems

The majority of TLE separations have so far been carried out in aqueous buffer systems similar to those

used in TLC. More recently, the use of nonaqueous systems has been shown to be useful in achieving faster and more efficient separations.

Potentials, Currents and Power Supplies

Potentials used in aqueous TLE are in the range of 10–100 V cm^{-1} , with currents of around 10–100 mA. This generates power levels of around 1–100 W. At the higher power levels, plate cooling is essential in order to prevent drying out. When nonaqueous systems are used, potentials between 200 and 2000 V cm^{-1} are used, with currents of 0.01–2 mA, generating between 0.02 and 20 W. Cooling of plates run at higher potential is seldom employed. Cooling is rarely necessary and very difficult to achieve due to the inherent incompatibility of high thermal conductivity and good electrical insulation characteristics in materials.

Starting Conditions

The layers are usually pre-wetted with the eluting solvent following sample application. This is achieved by spraying or dipping. Some experiments have been carried out using dry plates, but with limited success.

Sample Application and Visualization

The same methods of applying and viewing sample spots and bands used in TLC are employed in TLE.

Applications

Thin layer electrochromatography can be divided into three main forms depending on the major factor governing the separation. While not mutually exclusive, since most separations include some element of the other modes, these broadly arise from electrophoretic solute migration, electroosmotic solvent flow and the natural spin-off from the heating effects arising from the applied potential, electrothermal elution.

The most commonly encountered examples of TLE are based around electrophoretic separations in aqueous solvent. Not surprisingly, given the historical success of paper electrophoresis, several workers have used thin layers of microcrystalline cellulose. In addition, cellulose acetate and silica have been used for the separation of proteins. Other applications have included the separation of starches, amino acids (and various derivatives) (Figure 4), organometallic compounds (Figure 5) and transition metal ions.

Electrophoretic separations are not limited to aqueous solvent systems and the higher resistance of nonaqueous solvents gives the advantage of lower currents and reduced heating effects. The separation

Figure 4 The separation of amino acids by two-dimensional thin layer electrophoresis–thin-layer chromatography with an aqueous electrolyte. The chromatographic media was plastic-backed cellulose layer. Electrophoresis in the first dimension using a 4% (v/v) aqueous formic acid electrolyte was followed by chromatographic elution in the second dimension with butanol–0.4% pyridineacetic acid (22:10:10, v/v/v). Adapted from E. McEvoy-Bowe (1985) *Journal of Chromatography* 347: 199–208, with permission.

of a number of dyes using ethanol as the solvent is shown in **Figure 6**. In this separation electroosmotic flow effects were suppressed to reveal the electrophoretic migration of the charged dyes, resulting in completely different elution orders.

In TLE, solvent migration from EOF is easily confused with capillary-induced flow resulting from localized solvent evaporation. Broadly speaking, EOF is to be expected from wet polar solvents, protic solvents or from those that are capable of autoprotolysis.

With vertical tank systems, and particularly those employing nonpolar solvents, there must remain some uncertainty over whether thermal effects have been responsible for any solvent migration observed. This is the case in the pioneering planar systems studied by Pretorius (**Figure 7**), in which nonpolar solvents such as benzene were allegedly used. Our attempts to reproduce this work with a vertical tank system resulted in an electrically driven solvent

migration and chromatographic separation resulting largely from thermal effects and not EOF. By changing to more polar solvents, in a horizontal tank, we have shown that true electroosmotic flow could be achieved. The separation of a number of pyrimidines on silica eluted with ethanol showed elution characteristics similar to those obtained by conventional TLC, but with higher separation efficiency and in one tenth of the time (Figure 8).

More recently, high-voltage nonaqueous TLE employing electroosmosis as the main driving force has been applied to the separation of a wide range of acidic, basic and neutral organic compounds, with considerable success.

Development

The discovery that antigen–antibody interaction could be produced not only in liquids, but also on gel media, such as agar or agarose gels, with the formation of insoluble immunoprecipitates, opened the door to the development of the gel diffusion techniques for immunoprecipitation analysis. The first of these techniques, known as double diffusion, was introduced by Ouchterlony in 1948. In this technique, the antigens (proteins) and the corresponding antibodies (immunoglobulins, Ig) are located on a thin agar gel, in small and separated wells. The simple diffusion of the antigen and the antibody produce precipitation lines between the two wells where the interaction of these molecules occurs.

Advances in gel immunoprecipitation techniques occurred in 1953, when Grabar and Williams described immunoelectrophoresis (IE), in which the high resolution of electrophoresis and the specificity and sensitivity of the immunological reactants are combined. The immunoelectrophoretic techniques had a very rapid development during the 1960s and early 1970s, because they are adequately suited to the analysis of complex mixtures of proteins. The first attempts to improve the immunoelectrophoretic technique pursued two main objectives: to increase its speed (IE was rather slow, mainly due to the time-consuming immunodiffusion step) and to achieve quantitative methods (IE is basically qualitative).

In a short period of time new techniques based on crossed immunoelectrophoresis (CIE), rocket immunoelectrophoresis (RIE), counter IE, crossed-affinity IE (CAIE) and charge shift IE, were introduced.

This article describes all the techniques in which electrophoresis and immunoprecipitation steps performed in agar or agarose gels are combined. Diffusion-type techniques, such as double immunodiffusion and the quantitative radial immunodiffusion, will not be described. Other immunochemical techniques, such as enzyme-linked immunosorbent assay (ELISA) and Western blotting, in which immunoprecipitation is not produced, will be considered elsewhere.

Conventional Immunoelectrophoresis

The scheme in Figure 1A shows the principles of the techniques, such as it was originally introduced and generally used by many workers. The first step consists of electrophoresis in 1% agar-agar or agarose gels, prepared in different buffers at pH ranging from 8.2 to 8.6 (Veronal 0.025 mol L^{-1} , pH 8.2 is one of the buffers frequently used). The sample to be analysed, usually a complex mixture of proteins, is applied in small wells located in the middle of agar-agar gels, or partially displaced towards the extreme nearest to the cathode when agarose gels are used. Most of the proteins, for example in blood sera or plasma, have a negative net charge in buffers with pH higher than 7.0. Thus, when a continuous electrical field is applied to the gel, the tendency of these proteins is to move towards the anode with a migration rate which mainly depends on charge-to-size ratio. However, the migration rate is in part reduced by the electroendosmotic effect due to the negative charges in polymeric molecules of the gel. This electroendosmotic effect is greater in agar-agar than in agarose gels. The extension of the electrophoretic run can be precisely fixed by controlling the migration of a marker. One of the markers routinely used is the protein stain Amido black. The second step is a double immunodiffusion performed in the same gel plate (Figure 1A). For this, longitudinal channels are cut parallel to the direction of the electrical flow and separated 4 mm from the original wells where the samples were applied. The channels are filled with the

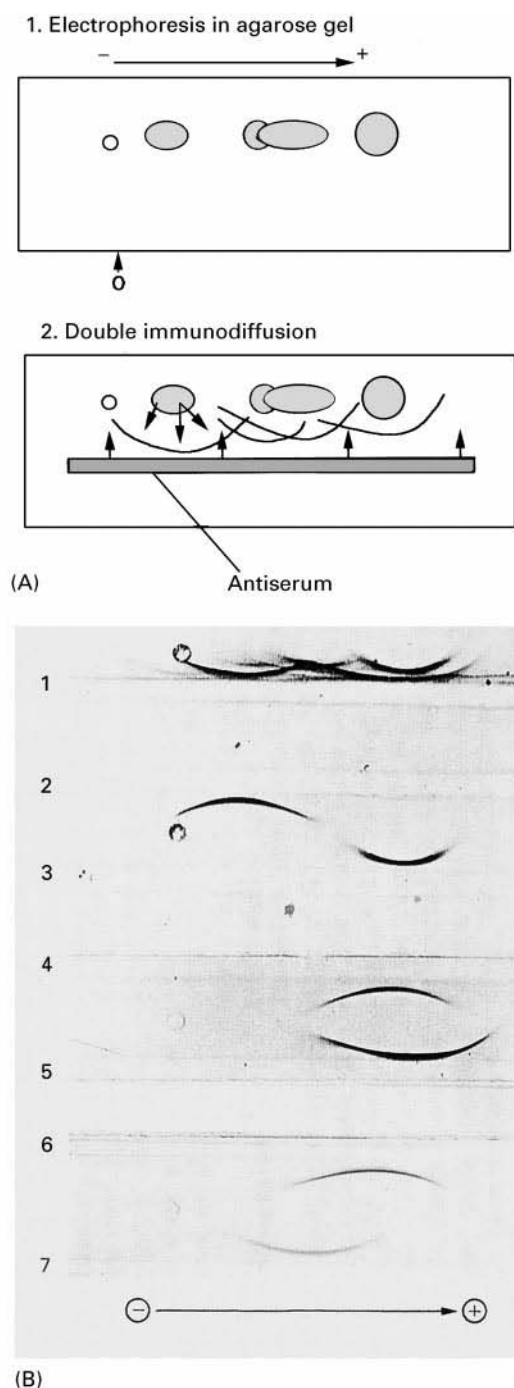

Figure 1 (A) Schematic representation of the principle of conventional immunoelectrophoresis. 1, Electrophoresis of the sample in agar or agarose gels; 2, double immunodiffusion of the separated proteins and the corresponding antiserum. (B) Application of the technique to the study of specificity of various antisera. In all wells, fetal pig serum was applied. In the channels, the following antisera were assayed: 1, anti-fetal pig serum, 2, anti-transferrin; 3, anti-albumin; 4, anti- α -fetoprotein; 5, anti- α_1 -antitrypsin; 6, anti- α_1 -acid glycoprotein; 7, anti-fetuin. (With permission from Lampreave, F, González-Ramón N, Martínez-Ayensa S, Hernández MA, Lorenzo HK, García-Gil A and Piñeiro A (1994) *Electrophoresis* 15: 672-676.)

corresponding antiserum and the plate is maintained in a humid, sealed box, for a period of between 24 and 48 h. Under these conditions, the combination of the radial diffusion of the proteins from the circular or ovoid spots obtained after the electrophoretic run, with the uniform diffusion of the antibodies, occurring in a perpendicular direction to the channel, produces arcs of precipitation in the different electrophoretic zones.

The IE patterns can be directly visualized or photographed, in the wet gel, by dark-field illumination. In this method the oblique light from a circular source placed below the plate is directed through the gel and transmitted at an angle of about 25° . The immunoprecipitates are visible as white lines on the dark background. To preserve the plates and before staining the immunoprecipitates, it is necessary to wash the gel plates extensively so that all the unprecipitated materials are removed. The wash is accomplished by immersing the gel plates in a buffered saline solution (0.01 mol L^{-1} phosphate, NaCl 0.15 mol L^{-1} buffer, pH 7.4) for 1-3 days, and with several changes of liquid. Alternatively, a quick procedure can be carried out by placing several paper towels on the gel plate and applying a moderate pressure for some minutes. In this way, the liquid and all the soluble material are removed from the gel and absorbed by the paper towels. Then, the plate is submerged in the saline solution until the gel almost recovers its original thickness. Repeating this drying/soaking cycle, it is possible to achieve effective and rapid washing of the plates. Finally, the plates are dried and the immunoprecipitates stained, commonly with Coomassie blue or Amido black. The sensitivity of the method, using these conditions, allows the detection of proteins with concentrations ranging from 3 to $20 \mu\text{g mL}^{-1}$. Specific staining methods have been introduced to facilitate the identification of single proteins. For example, Sudan black can be used to detect lipoproteins and periodic acid (Schiff reagent) for polysaccharides and glycoproteins. There are also specific staining procedures for some proteins, such as ceruloplasmin, hemopexin, etc.

IE has been used to analyse complex mixtures of proteins from tissue extracts; to detect impurities during the monitoring of protein purifications; to detect differential expression of protein during growth and differentiation; to study the expression of single proteins during pathological situations and to detect protein polymorphisms. Figure 1B shows an example of the application of the IE technique. In the plate, the specificity of different antisera against six proteins isolated from fetal pig sera (albumin, α -fetoprotein, α_1 -acid glycoprotein, α_1 -antitrypsin, fetuin and transferrin) is analysed by attaching them to

a fetal pig serum by this technique. As reference, the same fetal pig serum is analysed against a polivalent anti-fetal pig antiserum.

Counter Immuno-electrophoresis

This technique is a modification of conventional IE, that is performed in agar-agar gels at pH 8.0. Under these conditions, the antibodies are positively charged whereas the antigens present a negative net charge. Antigen and antibodies are applied in wells of 3 mm diameter, as indicated in **Figure 2**. Antibodies are placed on the well nearest to the anode and the sample in that close to the cathode. By applying a voltage across the gel the antigen and the antibodies move towards each other, forming lines of precipitation between the two wells. For this technique, the utilization of agar-agar gels is convenient since the medium, at the pH commonly used, generates a significant electroendosmotic flow that increases the cathodic movement of the antibodies. This technique can be used to detect both antigen and antibodies; rapidity is the main advantage.

Crossed Immuno-electrophoresis

Crossed IE is another approach in IE which is well suited for qualitative and quantitative analysis. The method, which was originally named two-dimensional electrophoresis or antigen-antibody crossed IE, offers not only higher resolution and simpler interpretation of the results than in conventional IE but it can also be standardized for quantitative analysis.

The principles of this technique are presented in **Figure 3A** and consist of two electrophoretic runs, both in 1% agarose gel plates. Veronal 0.05 mol L^{-1} pH 8.6, 1 mmol L^{-1} calcium lactate is a buffer that is frequently used. Samples are applied in wells of around 3 mm

diameter and a current applied for about 3–4 h at a potential gradient of 10 V cm^{-1} (to achieve a total electrophoretic run of around 6 cm). Afterwards, a longitudinal strip of 1 cm width, which includes the separated protein fractions, is cut off and transferred to a plate with the second agarose gel (prepared in the buffered solution as above) that contains the antiserum corresponding to the material to be tested.

The second run is carried out in a perpendicular direction to the first separation, at a potential gradient of around 5 V cm^{-1} . The time of this electrophoretic step varies depending on the mobility of the antigens. For complex mixtures, and depending on the relative proportions between antigens and antibodies, periods of around 6–10 h may be needed. Under these conditions, precipitation peaks are produced in which the height prevails over the width. Furthermore, the area of each peak is now related to the amount of protein contained in the sample.

Identification of proteins in the crossed immuno-electrophoretic patterns, though simpler than in the patterns obtained by conventional IE, presents difficulties when complex mixtures of proteins are analysed. For that reason, some modifications to crossed IE, such as fused rocket IE, line IE, tandem crossed IE, crossed line IE and crossed IE with intermediate gel, have been introduced.

Crossed IE techniques enable the easy comparison of the content of a determined protein in different samples. **Figure 3B** shows an example of the potential of this technique, applied to the study of the acute-phase proteins in pigs. The comparison of the crossed immuno-electrophoretic patterns of blood serum from the same pig before (left) and 48 h after the induction of acute inflammation by turpentine injection (right, acute-phase serum), permits detection of important differences in the concentration of some plasma proteins. Especially notable is the increase of peak 9, that corresponds to the major acute-phase protein in pigs, called Pig-MAP, which could be detected through this technique.

Crossed IE can also be applied to the study of membrane proteins. For this it is convenient to solubilize them with nonionic detergents, such as Triton X-100, that better preserve the structural and functional properties of these proteins. The detergent does not cancel out the antigenic properties of the membrane proteins, nor does it impede the antigen-antibody reaction. In the characterization of membrane proteins it is important to know whether the proteins studied possess hydrophobic domains that anchor them to the hydrocarbon interior of the bilayer, or whether they are externally bound to the membrane. Charge-shift immuno-electrophoresis permit the user to easily obtain that information even in

Figure 2 Principle of counter IE. This technique is developed in agar-agar gels, at pH 8.0. Antigens move towards the anode and antibodies to the cathode, due to its charge and to the electroendosmotic effect. (With permission from Lampreave F and Piñeiro A (1992) Concentration of major plasma proteins in serum and whole-tissue extracts of porcine fetuses during development, *Journal of Reproduction and Fertility* 95: 441–449.)

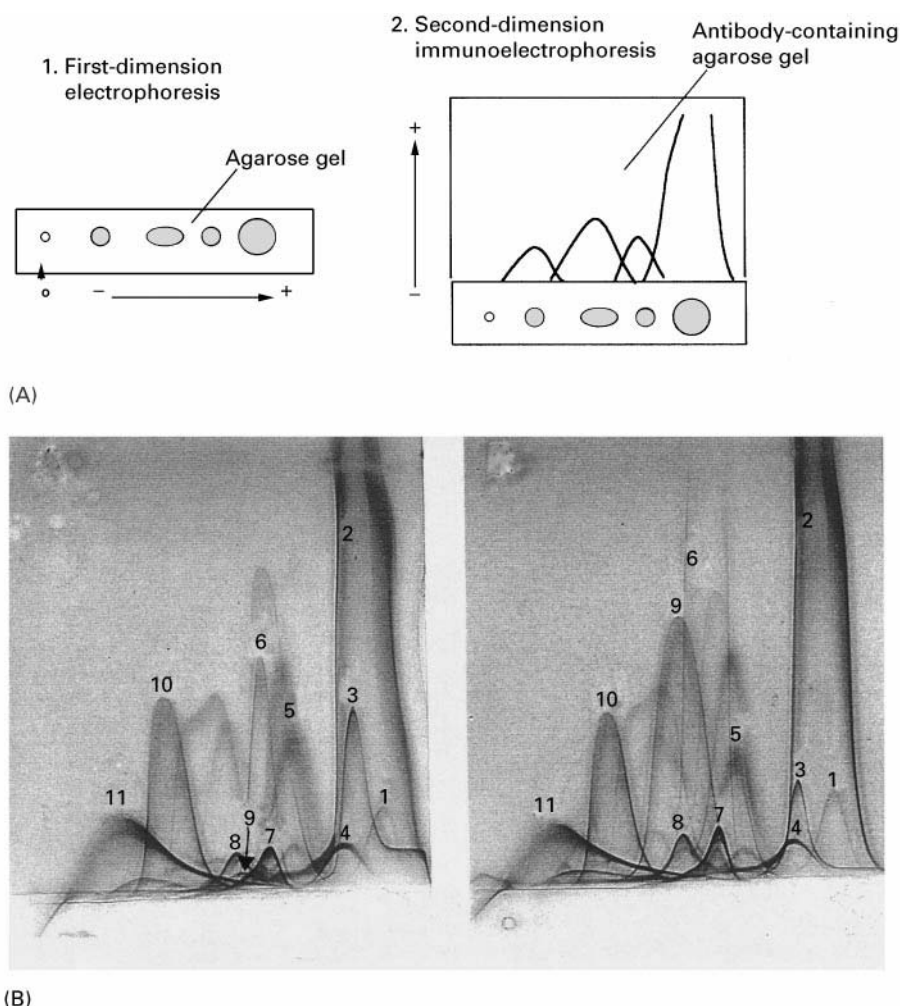

Figure 3 (See Colour Plate 41). (A) Schematic illustration of crossed IE. 1, Agarose electrophoresis of the sample (O = origin, corresponding to the well where the sample is applied); 2, a longitudinal strip of the first-dimension gel is transferred into a second-dimension gel containing a polyvalent antiserum. The second-dimension IE is performed perpendicularly to the first-dimension run. (B) Example of use of the crossed IE technique. The blood serum from the same pig is analysed (left) before and (right) 48 h after turpentine injection. The changes in the protein concentrations, induced by inflammation, can easily be studied by analysing the area (or height) of the different-numbered peaks. (With permission from Lampreave, F, Alava MA and Piñeiro A (1996) *Trends in Analytical Chemistry* 15: 122–129.)

complex mixtures. Membrane proteins are solubilized either with Triton X-100 alone or mixed with other detergents, for example, Triton X-100/sodium deoxycholate (an anionic detergent) and Triton X-100/cetyltrimethylammonium bromide (a cationic detergent). Afterwards, these three membrane extracts are analysed comparatively by crossed IE. The detergent-induced shift in mobility provides a method to distinguish between hydrophilic and amphiphilic proteins.

Rocket Immunoelectrophoresis

This immunochemical method, introduced by Laurell in 1966, is suitable for the quantitative estimation of

proteins. In this case (Figure 4A) there is only one electrophoretic run carried out in 1% agarose gel (plates of uniform thickness of about 1.5 mm) in Veronal buffer, pH 8.6 as described before, but including an appropriate quantity of an adequate antiserum. The samples are applied in separated wells of 3 mm diameter, located near the extreme of the plate in contact with the cathode. To obtain quantitative results, different dilutions from a primary standard (a solution of the purified protein of known concentration) or a secondary standard (a serum previously evaluated using a primary standard) are applied on the gel. The electrophoresis is accomplished over periods ranging from 4 to 6 h depending on the charge of

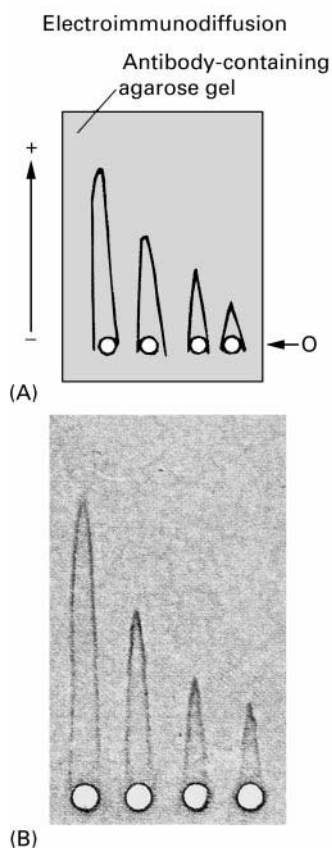

Figure 4 (A) Schematic representation of rocket IE. The electrophoresis is carried out in agarose gel containing specific antiserum against the protein to be determined. The area of the rockets (or its height) is proportional to the content of protein in the sample. (B) Application of this technique to the quantification of human α -fetoprotein. To improve sensitivity, the first immunoprecipitates (developed with rabbit antiserum to human α -fetoprotein) were treated with glucose oxidase-labelled sheep antibodies to rabbit immunoglobulins. From left to right, solutions containing α -fetoprotein concentrations of 720, 360, 180 and 120 ng mL⁻¹ were assayed.

the antigen and on the relationship between the amount of antigen and antibodies included in the gel plate. The immunoprecipitates formed in this case have the shape of a rocket, the area (or height) of which is proportional to the concentration of the antigen applied in the well. The concentration of the protein in unknown samples can be determined by reference to the calibration line obtained by representing the height versus the concentration of each standard.

This technique can be applied to any protein with a net charge that differs from that of the antibodies. Some proteins, such as, for example IgG, hardly move during electrophoresis using a pH 8.6 buffer. In these cases, the mobility of the antigen to be determined can be increased by carbamylation of the sample with KCNO.

Rocket IE is the most sensitive of the conventional immunelectrophoretic methods and allows one to accomplish the quantification of proteins (using stains to visualize the immunoprecipitates) up to concentrations close to 1 μ g mL⁻¹. This sensitivity can be increased by combining immunochemical methods. Figure 4B shows an example of one of these methods applied to determine human α -fetoprotein. During the electroimmunodiffusion, the first antigen-antibody reaction is produced using a rabbit antiserum containing the specific antibodies (Ig). In a second step, the plate is incubated with glucose oxidase-labelled sheep antibodies to rabbit Ig. Finally, the glucose oxidase bound to immunoprecipitates is revealed by incubating the plate with a solution that contains glucose, MTT-tetrazolium and phenazide methasulfate. The immunoprecipitates stain blue-violet over a fainter background of similar colour. This method provides reproducible results and allows the quantification of α -fetoprotein at concentrations as low as 50 ng mL⁻¹.

Crossed-affinity Immunelectrophoresis (CAIE)

Affinity electrophoresis refers to any technique in which two or more components specifically interact during an electrophoretic run. Affinity electrophoresis in agarose gels, combined with subsequent immunochemical detection (CAIE), was introduced by Bog-Hansen in 1975 as a useful tool for the characterization of biospecific macromolecular interactions. This technique permits, among other things, the demonstration of ligand-binding proteins, enumeration of binding sites and estimation of binding constants, with the added advantage of being adequate for determination of very small quantities in impure materials.

An important field of application of CAIE has been the study of the interaction of glycoproteins and lectins. Lectins are animal and mostly plant-derived proteins that specifically interact with the carbohydrate components of glycoconjugates. There is a considerable amount of information in the literature about the biochemical properties of numerous lectins and on the type of glycan structures that they can recognize. Using different lectins in the first electrophoresis run (affinity electrophoresis step), CAIE permits the analysis of the heterogeneity of glycoproteins in complex mixtures. The serum protein glycoforms, after fractionation by lectin affinity electrophoresis, can be revealed with specific antibodies and finally quantified.

Figure 5A shows a schematic illustration of the CAIE technique. First, the serum proteins are subjected to electrophoresis (generally at pH 8.2–8.6)

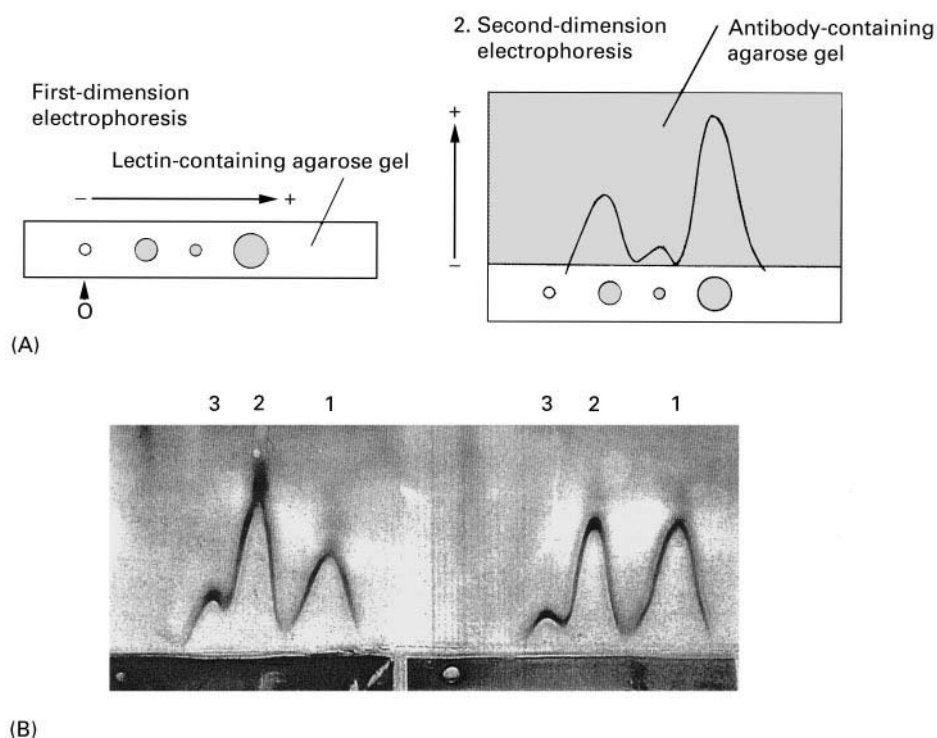

Figure 5 (A) Schematic representation of the CAIE technique. O, origin, corresponding to the well where the sample is applied in the first-dimension electrophoresis. (B) CAIE patterns of human α_1 -acid glycoprotein from (right) healthy individuals and (left) patients with inflammatory processes. The numbered peaks correspond to microforms of α_1 -acid glycoprotein in decreasing order of mobility.

in lectin-containing agarose gels (first-dimension gel). The lectin is added to the melted agarose (at around 55°C) before pouring the gel. Under these conditions most of the lectins used in CAIE do not have sufficient mobility. The proteins are fractionated in their different glycoforms, whose mobility depends on their corresponding affinity for the lectin. The first-dimension gel is then transferred into a second-dimension agarose gel containing specific antibodies against the protein to be analysed. The second-dimension electrophoresis produces for many serum glycoproteins fused precipitating peaks, which corresponds to the different microforms present in the sample. The CAIE patterns can be visualized by the methods described in the previous immunochemical techniques. The amount of each glycoform is related to the corresponding immunoprecipitating area that can be calculated by planimetry or by triangulation.

Figure 5B shows, as an example, the CAIE patterns of α_1 -acid glycoprotein from human serum. In the first dimension gel, 1 mg mL^{-1} of the lectin Concanavalin A was included. The second-dimension gel contained specific rabbit antiserum against human α_1 -acid glycoprotein. The different peaks have been labelled in decreasing order of mobility. Peak 1 corresponds to glycoforms of the human α_1 -acid glycoprotein that did not react with the lectin and contains tri- and tetra-antennary glycans; peak 2 corresponds to weakly

reactive glycoforms of the protein containing one bi-antennary glycan; finally, peak 3 corresponds to strong reactive glycoforms containing at least two bi-antennary glycans.

Equipment and General Methods

Agarose gels (1% w/v) are prepared in the described buffers on glass plates of different size according to need. For example $9 \times 12\text{ cm}$ plates are suited for conventional IE (they permit the analysis of eight samples or seven antisera) and also for RIE (in this case, about 20 samples can be applied). For the CIE and CAIE techniques, $4 \times 9\text{ cm}$ and $7.5 \times 10\text{ cm}$ glass plates can be used for the first and the second electrophoretic run, respectively. In all cases, one of the surfaces of the glass plates is coated with an agarose solution (1% w/v, in distilled water) that, after being dried, serves as an anchor for the agarose gel. To ensure regular thickness throughout the gel plate, which is essential for the reproducibility of quantitative methods, the melted agarose is poured between two glass plates separated by rigid spacers of around 1.5 mm thickness.

When antibodies, purified proteins or lectins are to be added to the gel, the agarose solution must be previously equilibrated around 55°C in a thermostated water bath to avoid protein denaturation. The

growth of microorganisms is avoided by the addition of preservatives to the agarose solutions, for example 0.1% sodium azide or 0.01% sodium merthiolate.

Simple equipment is commercially available, though much can be made in-house. The electrophoresis system only requires two electrophoretic tanks (provided with platinum wire and connected to the electrodes), and an adjustable power supply delivering voltage up to 400 V at 400 mA. The connection between the agarose plates and the buffer in the tanks can be accomplished through filter-paper wicks previously wetted in electrophoretic buffer (the same as that used for preparing the gel). To avoid excessive warming of the gel during electrophoresis, it is convenient to cool the agarose plates using a system connected to tap water. This allows the electrophoresis to be run at room temperature in the laboratory, alternatively, it can be carried out in a cold room at 5°C.

A great number of polyvalent and specific antisera prepared in goat, sheep or rabbits can be obtained from different suppliers or obtained in-house.

Present and Future Developments

Though most immunoelectrophoretic techniques described here were developed at least 25 years ago, they still enjoy great popularity and continue to be excellent tools for biochemists and immunologists. IE and CIE are very useful techniques for the characterization of complex mixtures of proteins and for the study of certain pathological situations that evolve with changes in plasma protein patterns. CAIE is a powerful technique for detecting glycoprotein microforms using different lectin specificities. Advances in the characterization of new lectins with restricted specificity represent a future development in this field. CAIE can also be applied to many affinity systems, including the important contribution of monoclonal antibodies in the affinity electrophoresis step.

Immunoelectrophoretic techniques are time- and antisera-consuming techniques. These limitations

could be improved by including the capillary methods commonly used in capillary electrophoresis systems.

Isoelectric Focusing

P. G. Righetti and A. Bossi, University of Verona, Verona, Italy

C. Gelfi, ITBA, CNR, Segrate, Milan, Italy

Copyright © 2000 Academic Press

Isoelectric focusing represents a unique electrokinetic method in that it is based on steady-state patterns

attained by amphoteric species (mostly proteins and peptides) along a pH gradient under the influence of an electric field. Due to a continuous balancing of diffusion away from the pI (isoelectric point) and pI-driven electric forces, extremely sharp zones are obtained, characterized by a very high resolving power. This article will consider conventional isoelectric focusing (IEF) in soluble, amphoteric buffers; and immobilized pH gradients (IPG) in insolubilized,

non-amphoteric buffers. In the latter case, guidelines will be given on how to optimize linear and nonlinear pH gradients and examples will be shown on the unique resolving power of the technique.

Conventional Isoelectric Focusing

In principle, pH gradients could be obtained by diffusion of non-amphoteric buffers but such 'artificial' gradients would be altered by changes in electric migration and diffusion of the buffer ions. Thus, Svensson in 1961 introduced the concept of 'natural' pH gradients, created and stabilized by the electric current itself. The buffers used in this system required two fundamental properties: first amphoterism, so that they could reach an equilibrium position along the separation column and secondly 'carrier' ability. This last concept is more subtle, but just as fundamental. Any ampholyte cannot simply be used for IEF; only a carrier ampholyte, that is a compound capable of transporting the current (a good conductor) and capable of carrying the pH (a good buffer). With this notion, and with Vesterberg's elegant synthesis of such ampholytes in 1969, present-day conventional IEF was born.

Some Basic Theoretical Concepts

Here some basic equations governing the IEF process will be considered. The most important is the one governing the distribution profile of an ampholyte about its isoelectric point. Under steady-state conditions (obtained by balancing the simultaneous electrophoretic and diffusional mass transports), Svensson derived the following differential equation describing the concentration profile of a focused zone:

$$C\mu i/qk = D\left(\frac{dC}{dx}\right) \quad [1]$$

where C is the concentration of a component in arbitrary mass units per arbitrary volume unit; μ is the electric mobility in $\text{cm}^2 \text{V}^{-1} \text{s}^{-1}$ of ion constituent except H^+ and OH^- , with positive sign for cationic and negative sign for anionic migration; i is the electric current in A; q is the cross-sectional area in cm^2 of electrolytic medium, measured perpendicularly to the direction of current; k is the conductance of the medium, in $\Omega^{-1} \text{cm}^{-1}$; D is the diffusion coefficient in $\text{cm}^2 \text{s}^{-1}$ of a given ionic component with mobility μ ; and x is the coordinate along the direction of current increasing from 0 to the anode towards the cathode.

Each term in eqn [1] expresses the mass flow per second and square centimetre of the cross-section: to the left being the electric and to the right the diffu-

sional mass flows. If eqn [1] is re-written in the form:

$$\left(\frac{i\mu}{q}\right)\left(\frac{dx}{k}\right) = D\left(\frac{dC}{C}\right) \quad [2]$$

it is seen that it is possible to integrate it if μ is known as a function of pH and D as a function of C . Specifically, if the conductance, the diffusion coefficient, and the derivative:

$$p = -\frac{d\mu}{dx} = -\left[\frac{d\mu}{d(\text{pH})}\right]\left[\frac{d(\text{pH})}{dx}\right] \quad [3]$$

(where p is the ratio between the protein titration curve and the slope of the pH gradient over the separation axis) can be regarded as constant within the focused zone, then $\mu = -px$ and one obtains the following analytical solution:

$$C = C_0 \exp\left[-\frac{(pix^2)}{(2qkD)}\right] \quad [4]$$

where x is now defined as being zero at the concentration maximum C_0 . This is a Gaussian concentration distribution with inflection points at:

$$x_i = \pm \sqrt{\left(\frac{qkD}{pi}\right)} \quad [5]$$

where x_i represents the width of the Gaussian distribution of the focused zone measured from the top of the distribution of the focused ampholyte to the inflection point (one standard deviation). The course of the pH gradient is $d(\text{pH})/dx$ and $d\mu/d(\text{pH})$ represents the titration curve of the ampholyte. It should be kept in mind that this Gaussian profile holds only if and as long as the conductivity of the bulk solution within the zone is constant. Constant conductivity along a pH gradient is quite difficult to maintain, especially as one approaches pH extremes (below pH 4 and above pH 10), if for no other reason, because the non-negligible concentration of H^+ and OH^- present in the bulk liquid begins to contribute strongly.

Another important equation regards the resolving power in IEF, expressed in $\Delta(\text{pI})$ units, i.e. in the minimum difference of surface charge between two adjacent proteins that the IEF technique is able to resolve. If two adjacent zones of equal mass have a peak-to-peak distance three times greater than the distance from the peak to inflection point there will be a concentration minimum approximating the two outer inflection points. Taking this criterion for resolved adjacent proteins, Rilbe derived the following equation for minimally but definitely resolved zones:

$$\Delta(\text{pI}) = 3\sqrt{\left(\frac{D[d(\text{pH})/dx]}{E[-d\mu/d(\text{pH})]}\right)} \quad [6]$$

This equation shows that good resolution should be obtained with substances with a low diffusion coefficient (D) and a high mobility slope [$d\mu/d(\text{pH})$] at the isoelectric point – conditions that are satisfied by all proteins. Good resolution is also favoured by a high field strength (E) and a shallow pH gradient [$d(\text{pH})/dx$]. It will be seen that, whereas in conventional IEF the limit to the resolving power is approximately 0.01, in IPGs it is 0.001 pH units.

The Carrier Ampholyte Buffers

Recall that the buffer capacity of an ampholyte in the isoprotonic state decreases with increasing ΔpK across the isoprotonic point, linearly at first, then exponentially. Let us take as an example a hypothetical ampholyte, with $\text{pK}_1 = 4.6$ (a carboxyl group) and $\text{pK}_2 = 6.2$ (an amino group), having thus a $\text{pI} = 5.4$ and $\Delta\text{pK} = 1.6$. If we titrate this ampholyte in the pH 4–7 range, encompassing the two pK s, and if we plot the accompanying buffering power (β), degree of dissociation (α) and slope of the pH gradient, we will have the plot shown in Figure 1(A). It can be seen that there is still a substantial buffering power at the pI of the ampholyte, with a corresponding degree of ionization less than unity, and that the titration curve is smooth throughout the pH gradient explored, with

only a small deviation about the pI of the ampholyte, indicating that this species is indeed a ‘good’ carrier ampholyte. Now take an ampholyte with $\text{pK}_1 = 4.6$ but with $\text{pK}_2 = 9.3$, thus with a $\text{pI} = 6.95$ and $\Delta\text{pK} = 4.7$. If we now titrate it in the pH 4–10 range, again encompassing the two pK values, we will have the graph shown in Figure 1(B). It can be seen now that at the theoretical pI value the ampholyte does not have any appreciable buffering power and that it is fully ionized. In addition, it is not only isoelectric at $\text{pH} = 6.95$, but indeed almost at any pH in the interval 5–9, as seen by the abrupt sigmoidal shape in the pI environment. This species will be a ‘bad’ carrier ampholyte, useless for a well-behaved IEF fractionation.

An important prerequisite for a good carrier ampholyte is that it has a high conductivity at its pI . Regions of low conductivity will absorb much of the applied voltage, thus reducing the field strength and hence the potential resolution in other parts of the gradient. It has been demonstrated that good conductivity is associated with small values of $\text{pI} - \text{pK}$. This is also true for the buffering capacity of an ampholyte. Thus, the parameter $\text{pI} - \text{pK}$ (equivalent to $\frac{1}{2} \Delta\text{pK}$) becomes the most important factor in selecting carrier ampholytes exhibiting both good conductivity and buffering capacity (β).

Methodology

The structure of carrier ampholytes (CA) and their general properties are illustrated in Figure 2. CAs are oligoprotic amino carboxylic acids, each containing at least four weak protolytic groups, at least one being a carboxyl group and at least one a basic nitrogen atom, but no peptide bonds. In a typical synthesis, a mixture of oligoamines (four to six nitrogens in length, linear and branched) reacts with an α - β -unsaturated acid (typically acrylic or itaconic acids), at a nitrogen–carboxyl ratio of 2 : 1.

The mechanism of developing a pH gradient in IEF is illustrated in Figure 3. Before passage of the current, the column is at constant pH (Figure 3A) and the multitude of amphoteric buffers is randomly distributed, resulting in a reciprocal neutralization. However, each individual CA species will have its own titration curve (see Figure 2, lower left side) defining different mobilities in the electric circuit. After starting the experiment the different CAs will migrate at different velocities in the column, the most acidic and most basic compounds being the fastest moving ions. As a result of this sorting process, a pH gradient will form, sigmoidal at first (Figure 3B), with an uneven voltage gradient. After 1 h, the various CA buffers will have separated further, and at this point an almost linear pH gradient has been established

Figure 1 Degree of ionization (α) and buffering power (β) of a good (A) and a poor (B) carrier ampholyte. (A) computer simulations obtained assuming a $\text{pK}_1 = 4.6$ and a $\text{pK}_2 = 6.2$ ($\text{pI} = 5.4$). The ampholyte was titrated in the pH 4–7 interval. (B) Computer simulation obtained by assuming a $\text{pK}_1 = 4.6$ and a $\text{pK}_2 = 9.3$ ($\text{pI} = 6.95$). The ampholyte was titrated in the pH 4–10 interval. Note the sharp sigmoidal transition in the pI region in (B), suggesting total lack of buffering power (Wenger P and Righetti PG, unpublished observations).

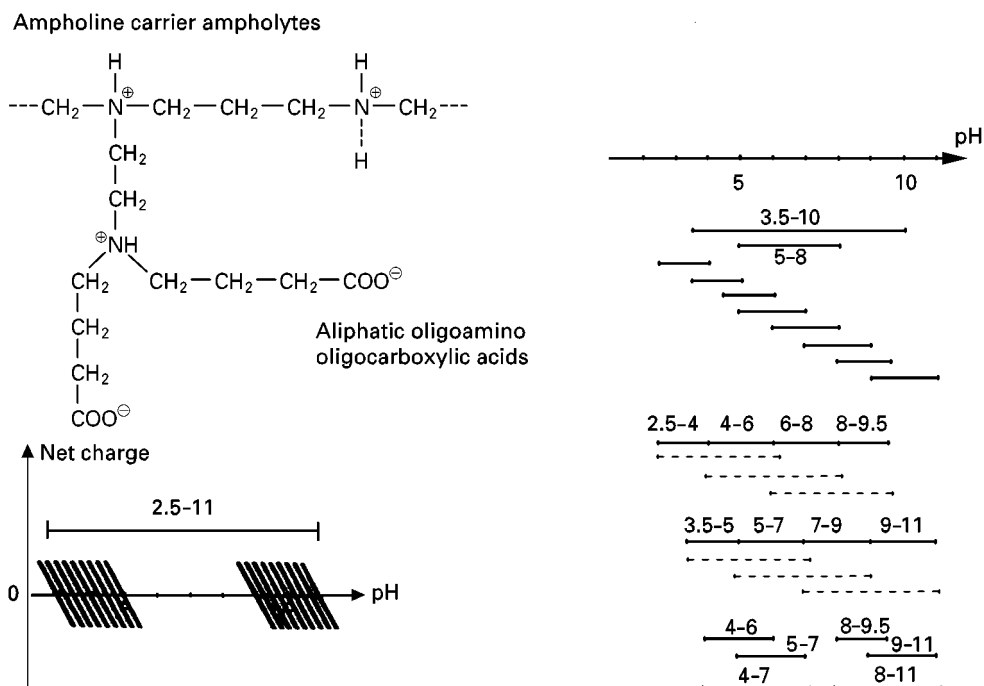

Figure 2 Composition of Ampholine. On the upper left side a representative chemical formula is shown (aliphatic oligoamino oligocarboxylic acids). On the lower left side, portions of hypothetical titration curves of carrier ampholytes are depicted. Right: different pH cuts for wide and narrow range ampholytes (by permission of LKB Produkter AB).

which spans the pH range defined by the pIs of the ampholytes (Figure 3C). After 1.5 h the CAs have separated into symmetrical zones with overlapping

Gaussian profiles. Now the system has achieved a steady-state, i.e. a balance between electrophoretic transport and diffusion away from the pI, and no

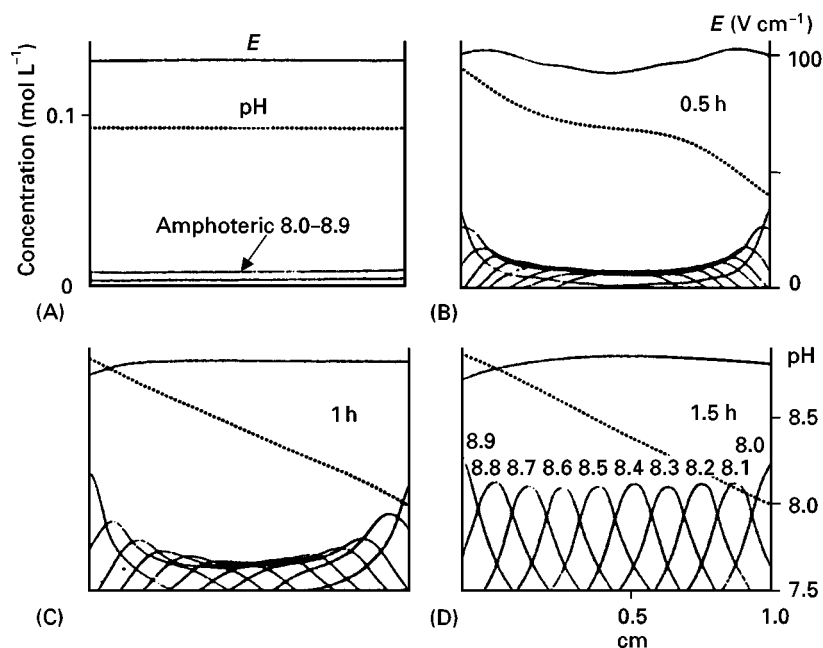

Figure 3 Calculated time development of a focusing process involving 10 ampholytes in a closed vessel. The p/s of the ampholytes are evenly distributed in the pH 8.0-8.9 range. The initial distribution of the amphoteric buffers is indicated in (A). The calculation was performed assuming a constant voltage (100 V cm⁻¹) across the system. The anode is positioned to the right in the diagrams. Each x-axis represents the distance from the cathode on the same scale as in (D). (Reproduced with permission from Schaefer-Nielsen, 1986.)

further mass transport is expected (Figure 3D). As long as the local concentration of the different CA species does not change the slope of the pH gradient will be kept constant with time. Proteins will keep migrating against this CA distribution profile eventually reaching their *pI* position.

By and large, most analytical IEF runs are performed in horizontal chambers: the polyacrylamide gel slab rests on a cooling block [generally made of glass or coated aluminium or even beryllium oxide (used as the heat shield of the space shuttle)]. This horizontal configuration allows one to dispose of electrode reservoirs and of all the hydraulic problems connected with vertical chambers (tight seals, etc.): in fact, anolyte and catholyte are soaked in filter paper strips resting directly on the open gel surface. In addition, most modern chambers contain a cover lid with movable electrodes which can be adjusted to any gel length (generally from 10 to 25 cm electrode distance). Since thick gels (e.g. 2 mm thick) generate thermal gradients through the gel thickness, resulting in skewed zones (essentially all horizontal chambers have cooling only on one gel face) ultrathin gels (0.2–0.5 mm) supported on a reactive polyester foil (Gel Bond PAG) are preferred today.

Immobilized pH Gradients (IPG)

IPGs are based on the principle that the pH gradient, which exists prior to the IEF run itself, is copolymerized, and thus immobilized within the polyacrylamide matrix. This is achieved by using as buffers a set of up to 10 non-amphoteric, weak acids and bases, called Immobilines, having the following general chemical composition: $\text{CH}_2=\text{CH}-\text{CO}-\text{NH}-\text{R}$, where R denotes either three different weak carboxyls, with *pK*s of 3.1, 3.6, and 4.6 (Table 1), or five tertiary amino groups, with *pK*s of 6.2, 7.0, 8.5, 9.3

and 10.3 (Table 2). This set of eight weak buffers is complemented by a strong acid (*pK* of approximately 1, 2-acrylamido-2-methyl propanesulfonic acid) and a strong base (*pK* > 12, quaternary aminoethyl-acrylamide), used only as titrants. During gel polymerization, these buffering species are incorporated into the gel (84–86% conversion efficiency at 50°C for 1 h), by the same free radical reaction used to activate the acrylamide double bond. Figure 4 shows a segment of a hypothetical structure of an Immobiline matrix and the process of focusing two proteins in it. It is seen that only the proteins migrate to their steady-state position, whereas the Immobilines remain fixed at their original grafting position in the gel, where a fixed ratio of buffering/titrant ions defines the pH locally. This means that the pH gradient is stable indefinitely (but it has to pre-exist before the onset of polymerization) and can only be destroyed if and when the polyacrylamide gel is hydrolyzed. Given the sparse distribution of Immobilines in the gel they behave as isolated charges, able to effectively contribute to the ionic strength of the medium. In conventional IEF, on the contrary, at steady-state the ionic strength is exceedingly low (less than 1 mequiv L^{-1}) since the focused carrier ampholytes form an inner salt, and this often results in protein precipitation and smears both at the *pI* and in its proximity. In IPGs the high ionic strength existing in the matrix (typically 10 mequiv L^{-1}) induces protein solubilization at the *pI* value (thus CA-IEF is similar to a 'salting-out' milieu and IPGs to a 'salting-in' environment).

Immobiline-based pH gradients can be cast in the same way as conventional polyacrylamide gradient gels by using a density gradient to stabilize the Immobiline concentration gradient, with the aid of a standard, two-vessel gradient mixer. As shown earlier, these buffers are no longer amphoteric as in

> 12	$\text{CH}_2=\text{CH}-\text{CO}-\text{NH}-(\text{CH}_2)_2-\text{N}^+(\text{CH}_2\text{H}_5)_3$	<i>N,N,N</i> -Triethylaminoethylacrylamide	198

conventional IEF, but are bifunctional: the buffering group is located at one end of the molecule and at the other end there is the acrylic double bond which will disappear during the grafting process. The three carboxyl immobilines have rather small temperature coefficients of ionization (dpK/dT) in the 10–25°C range due to their small standard heats of ionization (approximately 1 kcal mol⁻¹) and thus exhibit negligible *pK* variations over this temperature range. On the other hand, the four basic immobilines exhibit rather large ΔpK s in the same temperature range (as much as $\Delta\text{pK} = 0.44$ for the *pK* 8.5 species) due to their larger heats of ionization (6–12 kcal mol⁻¹). Therefore, for reproducible runs and pH gradient calculations, all the experimental parameters have been fixed at 10°C. Temperature is not the only variable that will affect immobiline *pK*s (and therefore the actual pH gradient generated): additives in

the gel that will change the water structure (chaotropic agents such as urea) or lower its dielectric constant, and the ionic strength itself of the solution, will alter *pK* values.

Narrow and Ultranarrow pH Gradients

We define the gradients (in the gel slab) from 0.1 to 1 pH unit as ultranarrow and narrow gradients, respectively. Within these limits one can generally work on a 'tandem' principle, i.e. choosing a 'buffering' Immobiline (e.g. a base or an acid), having its *pK* within the desired pH interval, and a 'non-buffering' Immobiline (e.g. an acid or a base), having its *pK* at least 2 pH units removed from either *pH*_{min} or *pH*_{max} of the pH range. The latter will therefore provide equivalents of acid or base, respectively, to titrate the buffering group, but will not itself buffer in the desired pH interval. For these calculations one

Figure 4 Hypothetical structure of an Immobiline gel and mechanism of the focusing process. The acrylamido acid and basic groups are shown grafted on the polyacrylamide matrix. Two proteins are shown migrating in the gel at the times $t = 0$, at $t = 1$ and finally at the steady-state, where they reach they respective *pI* values (*pI*₁ and *pI*₂) as points of zero net charge (by permission of LKB Produkter AB).

can resort to modified Henderson–Hasselbalch equations and to rather complex nomograms or simply adopt tabulated recipes, 1 pH unit wide, which start with the pH 3.8–4.8 interval and end with the pH 9.5–10.5 span, separated by 0.1 pH unit increments (58 such recipes have been tabulated). If a narrower pH gradient is needed this can be derived from any of the 58 pH intervals tabulated by a simple linear interpolation of intermediate Immobiline molarities.

Extended pH Gradients

For wider pH intervals, several buffering species have to be mixed and the situation becomes considerably more complex. This has been solved with the aid of computer programs designed specifically for this purpose. The basic findings are: first for generating a linear pH gradient the buffering power has to be

Figure 5 Effect of changes in the number of (evenly spaced) buffering components. The optimal concentrations of fictitious buffers (bases) with pK s differing by 1, 1.25, 1.66 and 2.5 pH units, were calculated so as to cover the pH 4.5–8.5 range. The resulting courses of β power are shown as a function of ΔpK . The insert is a plot of percentage variation, in comparison with the case $\Delta pK = 1$, of the ranges of deviation of pH (left scale) and of β (right scale). Note that the smoothest β power is obtained with $\Delta pK = 1$ (from Gianazza *et al.*, 1983, with permission of Elsevier Science Publishers).

Figure 6 Effect of changes in the pK of the acidic titrant. A reference Immobiline mixture was titrated to the same pH value with fictitious acids whose pK was 0.5, 1.0, 1.5, 2.0 and 2.5 pH unit lower than the gradient's limit (in this case, $pH_{\min} = 3.5$) and the pH course was calculated for the five cases. The insert is a plot of the percentage variation of deviation from linearity as the titrant's pK increases (from Gianazza *et al.*, 1983, with permission of Elsevier Science Publishers).

constant throughout the desired pH interval (this is best achieved when the pK values are spaced at 1 pH unit intervals, see Figure 5). Secondly, to avoid deviations from linearity, the titrants should have pK s well outside pH_{\min} and pH_{\max} of the wanted pH range (in general, at least 2 pH units removed from the limits of the pH interval) (see Figure 6). As a consequence of this, for pH ranges wider than 3 pH units, two additional Immobilines are needed as titrants: one strongly acidic ($pK < 1$) and one strongly basic ($pK > 12$). There are two ways of generating extended pH intervals. In one approach the concentration of each buffer is kept constant throughout the span of the pH gradient and 'holes' of buffering power are filled by increasing the amounts of the buffering species bordering the largest ΔpK s; in the

Figure 7 Non-linear pH 4–10 gradient. Ideal (dotted line) and actual (solid line) formulation courses. The shape for the ideal profile was computed from data on the statistical distribution of proteins p/s. The relevant histogram is redrawn in the figure inset (from Gianazza *et al.*, 1985; by permission of VCH).

other approach (varying buffer concentration) the variation in concentration of the various buffers along the width of the desired pH gradient results in a shift of their apparent pKs with a concomitant evening-out of the ΔpK values. With the available recipes, preparation of any Immobiline gel is now

a trouble-free operation, as all the complex computing routines have already been performed and no further calculations of any type are required.

Non-linear, Extended pH Gradients

IPG formulations have been given only in terms of rigorously linear pH gradients. While this has been the only solution adopted so far, it might not be the optimal one in some cases. Altering the pH slope in some portions of the gradient might be required in those pH regions overcrowded with proteins. The reasons for resorting to non-linear pH gradients are given in the histogram of **Figure 7**. With the relative abundance of different species it is clear that an optimally resolving pH gradient should have a gentler slope in the acidic portion, and a steeper course in the alkaline region. Such a general course has been calculated by assigning to each 0.5 pH unit interval in the pH 3.5–10 region a slope inversely proportional to the relative abundance of proteins in that interval. The ideal (dotted) curve in **Figure 7** was obtained by such a procedure. What is also important here is the establishment of a new principle in IPG technology, namely that the pH and density gradients stabilizing it need not be co-linear. The possibility exists of modulating the former by locally flattening of pH

Figure 8 IEF of conalbumin in an IPG pH 4.5–6.5 gradient. Gel: 5%T, 3%C polyacrylamide, equilibrated in 10% glycerol. All samples were applied in round basins punched through the gel thickness at the cathodic side as 20 μ L droplet (20–500 μ g protein). Staining with Coomassie Blue R-250 in ethanol/acetic acid in presence of copper sulfate. Notice that, although the gel thickness is only 0.5 mm, there is no overloading effect in such a wide interval of protein concentration (from Righetti PG and Ek K, unpublished observations).

Figure 9 Focusing of histones in an IPG pH 10–12 nonlinear interval. Gel: 6% T, 4% C polyacrylamide matrix, containing an IPG 10–12 gradient, reswollen in 7 M urea, 1.5% Nonidet P-40 and 0.5% Ampholine pH 9–11. The gel was run at 10°C under a layer of light paraffin oil at 500 V for the first hour, followed by increasing voltage gradients, after sample penetration, up to 1300 V for a total of 4 h. The samples (2 mg mL⁻¹, 50 µL seeded) were loaded in plastic well at the anodic gel surface. Staining with Coomassie Brilliant Blue R-250 in Cu²⁺. Histone samples (from left). (1) VII-S (Lys-rich); (2) VI-S; (3) II-AS and (4) VIII-S (Arg-rich, subgroup F), from calf thymus. The pI 10.6 marker (cytochrome C) is in track 5 on the right side (from Bossi *et al.*, 1994, by permission of Elsevier Science Publishers).

gradients for increased resolution, while leaving unaltered the latter.

Although only one example of a nonlinear extended pH gradient is given here, clearly the possibility exists of modulating in the same fashion any narrower pH interval.

Examples on the Resolving Power

What can IPGs achieve in practice? Figure 8 gives an example of a separation carried to the limit of a small-scale preparative load. Even when conalbumin is greatly overloaded, up to 500 µg in a single

track, no smears or precipitations occur, while faint bands become visible. Another interesting example, at the very limit of any focusing technique, is given in Figure 9. Here histones are seen focused at the steady-state in a very alkaline pH 10–12 gradient. It can be appreciated that all histones have a pI in the pH range 11–12, as they should, given their amino acid composition. Previous data obtained by conventional IEF had attributed to them pIs in the pH 9–10 interval, clearly grossly underestimated.

Introduction

Isotachophoresis (ITP) is one of the electrophoretic techniques useful for the analysis and isolation of ionic substances. The first successful analysis using this method was reported for alkali earth metals and amino acids by Longworth in 1953. The use of glass capillaries was first reported by Martin and Everaerts in 1967 after the successful separation of metal cations using a glass capillary by Konstantinov and Oshurkova in 1963 and of carboxylic acids using a paper strip by Schumacher and Studer in 1964. Although various names had been used for this method, the name ITP was proposed by Haglund in 1970 and has been widely accepted. It is interesting to note that the root of the present capillary electrophoretic methods is ITP.

An ITP separation is due to the different electrophoretic mobilities of the sample components in a similar manner to the other electrophoretic techniques. However, ITP has some characteristic features which distinguish it from the other electrophoretic techniques. This article, summarizes the theoretical background of ITP separations and then describes the analytical and preparative equipment used. Finally, separation strategies are given together with typical examples of ITP.

Electrophoretic Mobility and Velocity

Effective mobility μ of an ionic substance in a solution can be expressed as a function of many factors as follows:

$$\mu = f(m_0, K_a, \text{pH}, T, \eta, \varepsilon, I, K_s, C_{\text{comp}}) \quad [1]$$

where m_0 is the absolute mobility of a solvated ion, K_a the acid dissociation constant, pH the pH of the solution, T the temperature, η the viscosity of the solvent used, ε the dielectric constant of the solvent, I the ionic strength, K_s the stability constants of the complexes or ion pairs formed, and C_{comp} the concentration of the complex-forming agent or the ion pair-forming agent.

Eqn [1] shows that the effective mobility is a complex function of the properties of the sample ion, the solvent used and the coexisting ions. A basic idea of the electrophoretic separation is to vary the mobilities of the ions being separated by varying some of the factors in the above function.

The migration velocity of the ion $(v)_i$ can be expressed as:

$$v_i = \mu E \quad [2]$$

where E is the potential gradient of the electrical field. Consequently the difference of the electrophoretic velocities among separands is the driving force of the electrophoretic separation.

The name of 'isotachophoresis' comes from the Greek for equal (*iso, iso*) velocity (*tacho, tachoz*) sample dragging (*phoresis, foreesqai*). Although this name characterizes its principle as described later, if the sample velocities were the same throughout the migration process, there would be no separation.

Principle of ITP

Operational Electrolyte System and Separation Principle

Two different electrolytes (a leading and a terminating electrolyte) are used in ITP and this is the important point which distinguishes it from other electrophoresis method. A sample solution is injected at the boundary of the two electrolyte solutions as shown in Figure 1(A). The leading electrolyte is usually a pH-buffered electrolyte containing leading ions (L) with the same sign as the sample ions and appropriate counterions with pH-buffering ability. Usually, Cl^- and K^+ or NH_4^+ are used as the leading ions because of their large mobilities. The terminating electrolyte contains terminating ions (T) together with appropriate counterions.

For successful ITP separations, the effective mobilities of A and B in Figure 1 should fulfil the following relationship:

$$\mu_L > \mu_A > \mu_B > \mu_T \quad [3]$$

At the initial stage of migration, a homogeneous mixed zone (A + B) is formed as shown in Figure 1(B), where A and B migrate with different velocities under the same potential gradient. In this case, v_A is greater than v_B in the mixed zone. A forms a pure zone in the leading side of the mixed zone, and

Figure 1 Separation process in isotachophoresis. (A) Before migration. (B) Separation process forming a mixed zone AB. (C) Complete separation (a steady state). L, leading zone; A, B, sample zone; T, terminating zone; E, potential gradient.

B forms a pure zone at the terminating side of the mixed zone. After a while, the mixed zone diminished and the sample components A and B are separated to form independent zones (Figure 1C). It should be noted that the migrating zones differ from those in zone electrophoretic migration. Once they are separated, they never mix again and the zone lengths are kept constant according to the sample amount as long as the migration current is applied. This is the isotachophoretic steady state.

When the migration order is as shown in Figure 1(C), the following relations are valid:

$$\begin{aligned}\mu_{A,A} &> \mu_{A,B} \\ \mu_{B,A} &> \mu_{B,B}\end{aligned}\quad [4]$$

where $\mu_{A,A}$ and $\mu_{B,B}$ denote the effective mobility of A and B ions in the steady state zone and $\mu_{A,B}$ and $\mu_{B,A}$ denote the effective mobility of A ions in the B zone and that of B ions in the A zone. This relation keeps the boundary between A and B zones very sharp (self-sharpening effect).

At the isotachophoretic steady state where the zone lengths of all samples are constant and no mixed zone

remains, the following relations are valid for a constant current:

$$v_L = v_A = v_B = v_T \quad [5]$$

$$E_L\mu_L = E_A\mu_A = E_B\mu_B = E_T\mu_T \quad [6]$$

From eqns [3] and [6] the following relationships between the potential gradient of zones (Figure 1) apply:

$$E_L < E_A < E_B < E_T \quad [7]$$

Therefore the separated zones can be detected by the use of a potential gradient detector and a conductivity detector besides spectroscopic detectors.

It should be noted that the pH of the ITP system is different in the different zones. The pH buffering counterions are continuously supplied from the leading electrolyte, and they regulate the pH of the sample zones. Usually the following relationship is valid for an anion analysis:

$$\text{pH}_L < \text{pH}_A < \text{pH}_B < \text{pH}_T \quad [8]$$

The reversed relationship holds in a cationic analysis. The difference $|\text{pH}_L - \text{pH}_T|$ is usually less than 1 when the pH buffering counterion is selected properly. Since the pH of the zones are thus not constant in contrast to zone electrophoresis, the effective mobility dependence of the samples on the pH of the leading electrolyte cannot be estimated straightforwardly. And this makes the separation optimization of isotachophoresis difficult in comparison with zone electrophoresis.

The pH buffers conventionally used are summarized in Table 1 for anion analysis. To keep good buffering capacity of the leading electrolyte, the pH_L

Table 1 pH buffers used for anionic analyses

Buffer	pK_a	pH_L range
Glycylglycine	3.140	2.6–3.6
β -Alanine	3.552	3.0–4.0
ϵ -Aminocaproic acid	4.373	3.8–4.8
Creatinine	4.828	4.2–5.4
Histidine	6.040	5.4–6.4
Imidazole	7.150	6.4–7.4
TRIS ^a	8.076	7.4–8.4
Ammediol ^b	8.780	8.2–9.2
Ethanolamine	9.498	9.0–10.0

^aTRIS, tris(hydroxymethyl)aminomethane.

^bAmmediol, 2-amino-2-methyl-1,3-propanediol. These buffers are used to adjust the pH of an electrolyte containing a leading ion such as hydrochloric acid.

should satisfy the following relationship:

$$pK_Q - 0.5 < pH_L < pK_Q + 0.5 \quad [9]$$

where pK_Q is the pK_a of the buffers used. The maximum buffering capacity is obtained at $pH_L = pK_Q$.

The isotachophoretic steady state is achieved when the following four conditions are fulfilled:

- The leading and the terminating electrolyte are chosen properly to satisfy eqn [3].
- A constant migration current is applied.
- Mass balance of the counterion is kept: the molar amount of the pH buffer flowing into the sample zone in a unit time should be equal to the amount flowing out the sample zone.
- Electroneutrality is kept in each zone as in normal electrolyte solutions.

ITP is bidirectional in principle, since electrophoretic phenomena are bidirectional. In fact, isotachophoretic stacking zones can be formed simultaneously for anionic and cationic components in a sample when a suitable electrolyte system is chosen. In bidirectional ITP, the anolyte and the catholyte are the leading electrolyte and the terminating electrolyte for anions, and vice versa for cations.

Although the selection of the operational electrolyte system for bidirectional isotachophoresis is not too difficult, the difference between the pH of an anolyte and that of a catholyte is restricted.

Qualitative Analysis

The effective mobility of a sample component is uniquely determined under a given set of experimental conditions and this allows qualitative analysis. In practice, some qualitative indices have been proposed using some different definitions on the basis of the ratio of the potential gradients or the conductivities of the separated zones. We have proposed R_E , which is defined for the component A as follows:

$$R_{E,A} = E_A/E_L = \mu_L/\mu_A \quad [10]$$

Figure 2 shows the experimental definition of R_E values using step heights, where the asymmetric potential of the potential gradient detector (δh) is corrected by the use of an internal standard. By comparing such qualitative values of samples with those of reference standards, tentative qualitative analysis can be done. Additional information by a UV/VIS online detector may be useful. For exact identification, ITP zones are fractionated and the fractions analysed by independent analytical methods.

Quantitative Analysis

In ITP, the concentration of ions in the steady-state zone is determined by their effective mobilities and by the concentration of the leading ion. Therefore, dilute components in a sample are concentrated according

Figure 2 Isotachopherograms and experimental definition of R_E values. L, leading zone; A, B, C, sample zone(s); T, terminating zone; h , step height; δh , step height corresponding to an asymmetric potential of a potential gradient detector, which can be determined using theoretical R_E value of internal standard; R_E , corrected R_E value of sample. The subscript S denotes component A, B or C.

to Kohlrausch's regulating function and conversely the concentrated components are diluted during migration. The following relation is valid among the total equivalent concentrations of the samples (C^t):

$$C_L^t > C_A^t > C_B^t > C_T^t \quad [11]$$

The quantitative index is the time-based zone length as shown in Figure 2. The absolute zone length of the sample A (l_A in cm) can be defined as:

$$l_A = 1000n/(C_A^t \pi r^2) \quad [12]$$

where n is the amount of applied sample (moles) and r the radius (cm) of the separation tube at a detector.

The zone passing time, t (s) is equal to the actual zone length divided by the ITP velocity, v (cm s^{-1}). When both the sample ion and the buffer ion are monovalent, t_A can be expressed as follows:

$$t_A = Fn(1 + \mu_Q/\mu_A)/i \quad [13]$$

where F is the Faraday constant, μ_Q the mobility of the buffer ion, μ_A that of sample A, and i the migration current.

Instrumentation

Separation System for ITP Analyser

A typical diagram of ITP analyser is shown in Figure 3 for unidirectional ITP. A separation tube connecting two electrodes is made of polytetrafluoroethylene (PTFE) or fused silica, whose inner diameter is 0.2–0.5 mm. A PTFE tube as large as 1 mm inner diameter is frequently used before detection as a pre-column to increase column hold up or electric charge for better resolution. An additional leading electrode chamber can be used to apply high current during pre-separation to reduce analysis time. The chamber is connected appropriately to the separation tube before the detector. The leading and the terminating electrode chamber are typically 20 mL in volume.

The separation tube is also filled with a leading electrolyte and a terminating electrolyte. The boundary is formed at a sample injection port and a sample solution is introduced there typically by using a microsyringe. Sample components are separated during migration and their zones are detected using appropriate detectors.

Detectors

The quality of the detector employed determines and limits the qualitative and quantitative analysis of ITP.

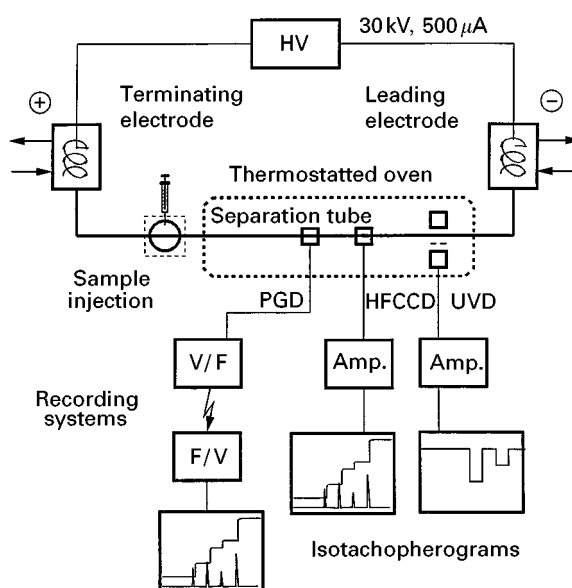

Figure 3 ITP apparatus with potential gradient detection (PGD), high-frequency contactless conductivity detection (HFCCD), and ultraviolet detection (UVD). HV, high-voltage power supply (constant current); V/F, voltage-frequency converter; F/V, frequency-voltage converter.

There are two demands on the detector; firstly to accurately reflect the separation occurring in ITP and secondly to obtain the isotachopherogram from the analysis with high reproducibility.

Detectors for ITP can be divided into universal and specific types. The signal from universal detectors is directly proportional to the effective mobilities of the ionic species, and these detectors detect zones of all components separated in the narrow-bore tube. Thermometric, potential gradient and conductivity detectors belong to this class. The detection limit of potential gradient and conductivity detectors is sub-nanomole but that of thermometric detector is rather high. On the other hand, specific detectors such as UV spectrophotometers allow the identification of some components directly, or at least can give additional information about zones.

In Figure 3, three detection systems using a high-frequency contactless conductivity detector (HFCCD), a potential gradient detector (PGD), and an ultraviolet detector (UVD) are shown. Since the sensing electrodes of PGD directly contact the solution in the capillary, this system needs a device to isolate high voltage. In Figure 3, a photocoupler is used for this purpose (IP-1B, IP-2A, IP-3A, Shimadzu, Kyoto, Japan, production discontinued). A transformer is used in the usual (contact type) conductivity detection (a.c. method). Although the sensitivity of a contactless detector is lower than the direct contact

detector, the merit of HFCCD is obviously that the detection system needs no such isolation device.

Preparative ITP Apparatus

Capillary type ITP is useful not only for analytical purposes but also for preparative purposes. Capillary type (CITP) is useful for batch processing of a small amount of sample.

In addition to direct cutting of the capillary section containing the target of interest, preparative methods in CITP can be classified into three types, as shown in Figure 4. Figure 4(A) shows a preparative ITP system reported by Arlinger for the fractionation of the entire sample zones. This system was used in the LKB Tachofrac (Bromma, Sweden, 1983, production discontinued). The zones were swept gradually by a counterflow of a leading electrolyte (ex. $3 \mu\text{L min}^{-1}$) on applying migration current, and the fractions were fixed on a cellulose acetate strip. The separated zones were successively pushed out through a T-branch by applying a counterflow and the zones were continuously fixed on the strip by an electric spray. The linear

velocity of the counterflow was set only a few percent higher than the isotachophoretic migration velocity so as not to dilute the sample by the leading electrolyte. The fractions on the strip can be analysed by immunological and radioactive methods. The zymogram technique can be used directly on the strip. The fractions have to be eluted, for analysis by other methods.

A dropwise fractionating method was developed utilizing a counterflow technique. The schematic diagram of the apparatus is shown in Figure 4(B). When the sample zone is pushed out from a T-branch, a spray effect is usually observed due to electrostatic forces. This can be a convenient interfacing technique but it disturbs dropwise fractionation. The electric spray and fluctuation of the drop rate due to electrostatic forces are suppressed by a very simple electrostatic device: As shown in Figure 4(B), the exiting fraction is surrounded by a copper coil, which is connected to a nozzle. The fractions are collected directly into small test tubes on the fraction collector through the coil. By using this technique, complete recovery of the mobile components in the injected samples is possible with minimum risk of loss and contamination. It should be noted, however, that mixing of adjacent sample zones cannot be avoided. The average volume of one drop was ca. $5 \mu\text{L}$ and the deviation was estimated as $+10\%$. A few nanomoles of the sample components are contained in a drop. The concentration of samples in the fractionated drops or the amount of the target in a fraction was adjustable by changing the flow rate of the leading solution. A typical counterflow of a leading electrolyte was ca. $12 \mu\text{L min}^{-1}$, which is much higher than the Arlinger-type apparatus.

Figure 4(C) shows another method reported by Kobayashi *et al.*, where the separated sample zones are discontinuously isolated by using a microsyringe. Kobayashi *et al.* used a potential gradient detector (PGD) with a sample-removal port to fractionate the target zone immediately after the tail of the zone was detected by the PGD. Although the method was not intended for the successive fractionation of the entire sample zones, the ease of operation is notable. This technique was employed for IP-1B and IP-2A instruments (Shimadzu, Kyoto, Japan, production discontinued).

Figure 4(D) shows other discontinuous fractionation technique using a specially designed fractionating valve placed at the end of the separation capillary. After trapping the target zone in the valve, the zone is flushed out.

In addition, the separation tube used was a series of four separation tubes (inner diameter of the tubes, 5–0.5 mm) in order to increase the amount of

Figure 4 Preparative methods in capillary-type isotachopheresis. (A) Arlinger's counterflow method. (B) Modified Arlinger's method. (C) Microsyringe method. (D) Fractionation valve method. sample separated. The tube of 5 mm inner diameter was made of acrylic resin and the maximum injectable sample volume was 2.5 mL.

Free-flow apparatus Since no solid media are used in free-flow electrophoresis (FFE), the most important point in instrumentation is the stabilization of the separated zones for any electrophoresis mode. Unstable zones may be caused by unstable operational electrolyte, sample flow, heat convection, density-driven flow, electroosmosis, etc. Bier *et al.* and Thormann *et al.* summarized several different methods for stabilizing the zones. A flat-type FFE is treated here, although there are several different approaches using different geometries, such as a thin film between parallel plates, a cylindrical laminar flow between two coaxial cylinders, etc.

Continuous FFE apparatus utilizing a thin flowing fluid was originally designed by Hanig for zone electrophoresis. Prusik and Wagner *et al.* designed and constructed similar apparatus, suggesting that several modes of electrophoresis can be used. At present, the only FFE apparatus available is the Octopus continuous electrophoresis apparatus from Dr. Weber GmbH (Kirchheim-Heimstetten, Germany). By using this apparatus, up to several grams of pure substances can be prepared daily, although the amount depends on the properties of the sample. Figure 5 illustrates the electrolyte circuits of an FFE system (Octopus)

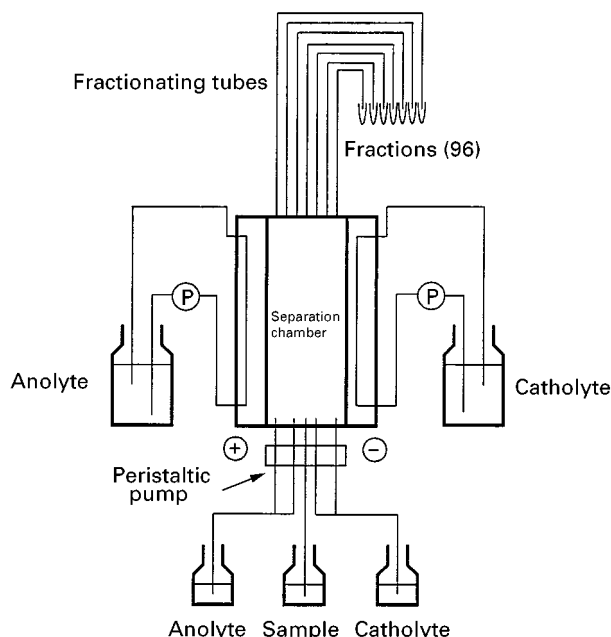

Figure 5 Electrolyte circuits of a free-flow electrophoresis apparatus (Octopus, Dr. Weber GmbH). Outer dimensions of separation chamber are $640 \times 180 \times 80$ mm, Separation area is 500×100 mm (variable thickness 0.4–2.0 mm). P, pumps.

when operated in continuous free-flow isotachophoresis (CFFITP) mode. The effective size of a typical separation chamber is 10-cm wide, 50-cm high and 0.4-mm thick. The sample solution is supplied with a multifold peristaltic pump together with an anolyte and a catholyte. Overflow of the separation chamber is collected as 96 fractions. The flow rate is variable in the range $0.3\text{--}100\text{ mL h}^{-1}$. The sample residence time is variable in the range 1–40 min. High flow rate and small residence time allow stable flow and consequently stable position of zones.

The anolyte and catholyte are circulated by pumps during migration. A dialysis membrane isolates the separation chamber from the electrode compartments. The electrolyte solutions may be denatured (the pH will change) after a few hours operation. The separation chamber can be thermostatted and separation can be monitored with a VIS CCD detection system which can be positioned near the end of the chamber. To obtain pure fractions, the positions of the sample zones at the end of the sample chamber should be stable. The positions are dependent on several factors such as the electric field strength, temperature of the electrolytes, flow rate, and sample and buffer composition. Since these factors are closely correlated with each other, careful control is needed. Sufficient residence time and separation distance are necessary especially when mobility differences are small. For this purpose, a larger separation chamber or a counterflow technique should be used as reported by Prusik (a 50×50 cm square chamber with a thickness of 0.5 mm).

Separation Strategy and Typical Applications

Operational electrolyte conditions should be optimized to obtain the best quality of separation by changing electrolyte parameters so that the difference of the effective mobilities of the target components should be as large as possible. Strictly speaking, the separability depends on the mobility difference in the mixed zone (see Figure 1). However, to a first approximation, the mobility differences at the steady state or the difference of the R_E values may be used for the criterion for optimization of separations.

For separation optimization in electrophoresis, a theoretical approach is sometimes very useful. In isotachophoresis especially, the pH and the ionic strength of the separated zones are different to one other. The optimum electrolyte system can be determined by iterative computer calculations where the effective mobilities of the species being separated at the steady state are calculated using their

physicochemical constants, and the differences of the effective mobilities compared. This method may be called computer-aided separation optimization, which enables the determination of the electrolyte conditions such as the pH without time-consuming 'trial-and-error' experiments. Some examples of simulation are also included in this section.

pH Effect

When the sample contains weak electrolytes, the pH of the leading electrolyte (pH_L) should be carefully chosen to obtain high separability among the components, since the effective mobilities of weak electrolytes change drastically according to the pH of the solution. This pH effect on the effective mobility is the most important and should be examined first.

Figure 6 shows the simulated and the observed isotachopherograms for a test mixture of pyrophosphoric (P_2O_7), triphosphoric (P_3O_{10}), tetraphosphoric (P_4O_{12}) acids, and 15 nucleotides, AMP, ADP, ATP, CMP, CDP, CTP, GMP, GDP, GTP, IMP, IDP, ITP, UMP, UDP and UTP. The pH_L was adjusted to 4.7 with creatinine. The optimum pH_L range was rather limited, because CTP may form a mixed zone with

UDP at low pH_L and with ATP at the high pH_L . Obviously from this example, the pH of the leading electrolyte should be carefully chosen in order to obtain high separability for weak electrolytes. For this purpose, computer simulation of the isotachophoretic steady state is useful, when the mobility and dissociation constants are available. In fact, the optimum pH_L of the above separation has been determined by simulation.

Solvent Effect

Since the mobility is strongly affected by the viscosity of the solvent and the dissociation constants depend on the dielectric constant of the solvent, the use of a nonaqueous solvent or a mixed solvent may improve electrophoretic separations (the solvent effect). The other advantage of the use of a nonaqueous systems is that it enables the analysis of substances with low water solubility. Many solvents have been successfully applied for isotachophoresis, such as methanol, ethanol, dioxane, acetone, propanols, dimethylformamide, etc. The migration behaviour in a nonaqueous solvent is very different from that in an aqueous solvent. The use of a mixed solvent

Figure 6 Simulated and observed isotachopherograms of 19 anions, AMP, ADP, ATP, CMP, CDP, CTP, GMP, GDP, GTP, IMP, IDP, ITP, UMP, UDP, UTP, pyrophosphoric acid (P_2O_7), triphosphoric acid (P_3O_{10}), tetraphosphoric acid (P_4O_{12}) and propionic acid (Prop) at $\text{pH}_L = 4.7$ (creatinine buffer). The terminator was pelargonic acid (Pel). Current, $75 \mu\text{A}$. Sample amounts, 1.2–3 nmol. The leading electrolyte contained 0.2% hydroxypropylmethylcellulose (HPMC). Buffer, creatinine. C_L^+ , concentration of leading ion.

(aqueous–nonaqueous) provides further possibilities for mobility control to improve separations.

Figure 7(A) and (B) show the simulated and observed isotachopherograms at pH 8 using triethanolamine buffer when methanol is used as solvent. The leading ion is perchlorate. Obviously, the separation is complete. On the other hand, insufficient separation was predicted for the aqueous system where the leading ion was chloride when $\text{pH}_L = 3.6$ (β -alanine buffer), as shown in Figure 7(C). Apparently the step heights of 2-naphthalenesulfonate, picrate and *o*-chlorobenzoate were similar and they may form a mixed zone in the actual analysis. No satisfactory separation was estimated when pH effects in the aqueous system were used.

Thus it is evident that the separation behaviour in isotachophoresis is strongly affected by the solvent used. As demonstrated above, high separability can be expected by the use of methanol solvent for particular samples but it should be noted that carboxylic acids are esterified gradually on standing in methanol solution, although the production of esterified compounds during analysis is negligible.

Complex-forming Effect

The use of a complex-forming agent is a traditional technique to improve separability especially in the case of metal ions. To achieve complex-forming equilibria, a constant amount of the complex-forming agent should be supplied continuously to the sample

zone. The complexing agent can be supplied as the counterion in the leading electrolyte, as neutral ligand (crown ether and cyclodextrin), or as the terminating ions.

Complex formation is very useful for the separation of metal ions. A typical example of the isotachophoretic separation of metal ions utilizing the complex-forming effect was reported for lanthanides, where α -hydroxyisobutyric acid (HIBA) was used as the complexing agent. The concentration of the complexing agent and the pH of the leading electrolyte should be optimized to obtain a good separation. By adding malonic acid to the main agent HIBA, 15 rare-earth ions (lanthanide and yttrium) were successfully separated as shown in Figure 8.

Conclusion

Isotachophoresis is a useful analytical technique with high reproducibility. However, ITP is not a very familiar technique to many chromatographers. Possible reasons are absolute sensitivity of ITP is in the sub-nanomole range, which is low in comparison with recent capillary electrophoresis (CE) techniques; auto-samples are not available; and stepwise recording is not readily accepted by chromatographers. However, it should be noted that the relative sensitivity of ITP is comparable with CE especially when the detection method is the same (e.g. UV detection), since a relatively large volume of a sample (e.g.

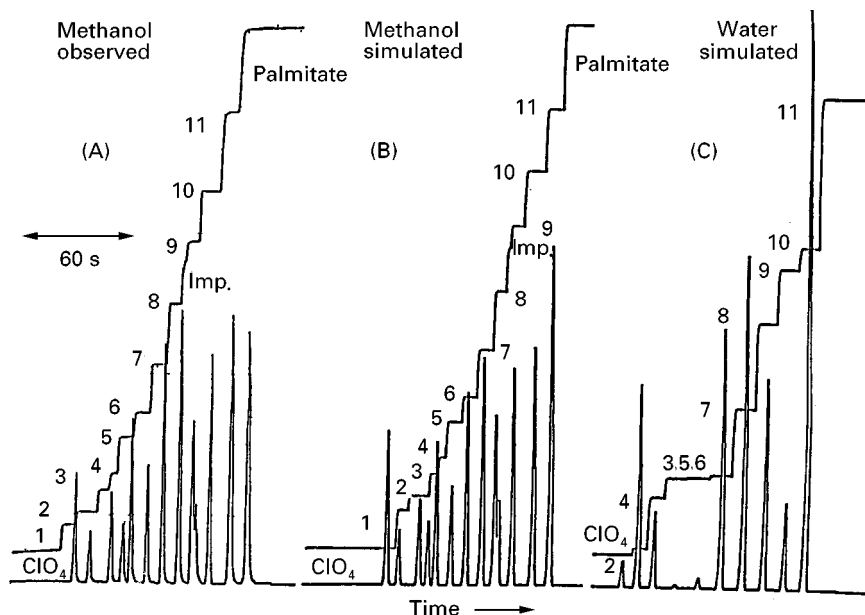

Figure 7 The observed (A) and the simulated isotachopherogram (B) of (1) bromide, (2) chloride, (3) picrate, (4) formate, (5) 2-naphthalenesulfonate, (6) *o*-chlorobenzoate, (7) *p*-chlorobenzoate, (8) 3-hydroxybutyrate, (9) crotonate, (10) propionate and (11) pelargonate ions in methanol as solvent. The leading ion was $10 \text{ mmol L}^{-1} \text{ ClO}_4^-$ and the buffer used was triethanolamine ($\text{pH}_L = 8.06$). Micellar Electrokinetic Chromatography

M.-L. Riekkola, Laboratory of Analytical Chemistry, University of Helsinki, Finland

Introduction

Micellar electrokinetic capillary chromatography (MEKC), first introduced by Shigeru Terabe and co-workers in 1984, has extended the potential of

capillary electromigration techniques to the separation of uncharged analytes. With its impressive separation efficiency and flexibility, MEKC has become a popular technique especially in the pharmaceutical and biomedical fields.

Above their critical micelle concentration (CMC), surfactant monomers added to an electrolyte solution form aggregates called micelles. Individual micelles are not significantly larger than the solutes being separated. On account of their small size and large number, they have a high surface area-to-volume ratio. Their structures are dynamic, with the average residence time of a surfactant monomer in the micelle being in the order of 1 ms or less. Separation in MEKC is based on the partitioning of analytes between the micelles and the aqueous phase, in the presence of electroosmotic flow. The micelles act as a pseudo-stationary phase. The mechanism of the analyte-micelle interaction is mainly determined by hydrophobic and electrostatic interactions. MEKC was originally developed to exploit the advantages of capillary electrophoretic techniques (high efficiencies, the requirement of only minute amounts of sample and reagent, fast analysis time) in the separation of neutral solutes of closely similar structure, but it is also applicable to the separation of charged

compounds. A basic capillary electrophoresis (CE) instrument is used, and the separations are carried out usually in uncoated fused silica capillaries after hydrodynamic injection.

Separation in MEKC

When one or more micelle-forming surfactants are added to the electrolyte solution at concentrations above their CMC, partition of the analytes into the micellar pseudo-stationary phase increases the selectivity of the separation system. The overall separation of compounds is based on their differential solubilization into the micelles and on the migration velocities of the micelles under the electric field, in the presence of electroosmotic flow (EOF). The separation principle for an anionic surfactant is illustrated in Figure 1.

The separation of neutral analytes is based on their partitioning between the aqueous phase and the micellar stationary phase. When solutes interact strongly with the micelles their migration time is comparable to that of the micelles, t_{mc} , allowing the solutes to serve as micelle markers. Neutral analytes migrate with times t_1 and t_2 , which lie inside a window formed by the migration times of the neutral

Figure 1 Schematic depiction of separation in micellar electrokinetic capillary chromatography.

Figure 2 Migration window for neutral solutes in micellar electrokinetic capillary chromatography. EOF, electroosmotic flow.

electroosmotic flow marker, t_{eo} , and the micelle marker, t_{mc} (Figure 2). A relatively polar molecule (e.g., acetone, acetonitrile, formamide, methanol, 1-propanol or tetrahydrofuran) can be used as electroosmotic flow marker, and usually a highly hydrophobic, neutral compound such as Sudan III, Sudan IV, dodecanophenone, Orange OT, or Yellow OB as micelle marker. The migration window is finite because the micelles themselves migrate out of the capillary. Even though the peak capacity is restricted by the migration window, high separation efficiencies can be achieved. A wide migration time window is favourable for high resolution, but then a long analysis time may be required.

The micellar phase is not a true stationary phase because it is moving along the capillary towards the detector. When the analyte is permanently retained, its migration time (t_m) is identical with the migration time of the micelle (t_{mc}). Therefore, the term 'retention factor' used in chromatography should be replaced by the term 'partition factor' in MEKC. The partition factor k_{mekc} is described as:

$$k_{mekc} = \frac{n_{mc}}{n_{aq}}$$

where n_{mc} and n_{aq} are the numbers of the analytes in micellar and aqueous phases, respectively. In the case of a neutral analyte, k_{mekc} can also be calculated directly from the migration times:

$$k_{mekc} = \frac{t_m - t_{eo}}{t_{eo}(1 - t_m/t_{mc})}$$

However, there may be variations in k_{mekc} depending on EOF and the micelle marker; in particular, the

choice of the micelle marker may have a significant effect on the value.

The selectivity α can then easily be determined by the ratio of the partition factors of two compounds:

$$\alpha = \frac{k_{mekc2}}{k_{mekc1}}$$

The most effective way to alter the selectivity of nonpolar analytes in MEKC is to change the micellar phase by changing the type of surfactant. When compounds are neutral, factors such as concentration of electrolyte and micellar solutions, pH, voltage and temperature have a relatively minor effect on the selectivity of the system. When the compounds are charged, on the other hand, variations in pH may induce changes in the dissociation of the compounds, affecting their charge, and thereby the solute-micelle ionic interactions and electrophoretic mobilities.

The resolution in MEKC is determined by the equation given by Terabe *et al.*:

$$R_s = \frac{\sqrt{N}}{4} \left(\frac{\alpha - 1}{\alpha} \right) \left(\frac{k_{mekc2}}{1 + k_{mekc2}} \right) \left(\frac{1 - t_{eo}/t_{mc}}{1 + (t_{eo}/t_{mc})k_{mekc1}} \right)$$

where N is the plate number. The resolution of the system depends on the efficiency, the selectivity, the partition factor and the migration time window.

Surfactants

Unique selectivities are achieved in MEKC through appropriate choice of anionic, cationic, nonionic and zwitterionic surfactants (Table 1). Surfactants are molecules with distinct hydrophobic and hydrophilic parts. The CMC increases dramatically with the alkyl chain length of the surfactant. At Kraft temperature, T_{Kr} , the solubility of the surfactant increases rapidly. T_{Kr} is the point at which surfactant solubility equals the CMC. The Kraft point varies with the surfactant, increasing with the length of the alkyl chain. Surfactant concentrations above the CMC and temperature above the Kraft point are required for the formation of micelles. Changes in temperature, concentration of surfactant, pH, ionic strength, additives in the aqueous phase and structural groups in the surfactant may cause changes in the size, shape and aggregation number of the micelles. In aqueous media, surfactants with bulky or loosely packed hydrophilic groups and long, thin hydrophobic groups tend to form spherical micelles, while those with short, bulky hydrophobic groups and small, close-packed hydrophilic groups tend to form lamellar cylindrical micelles. Factors that decrease the electrostatic repulsion between the head groups of ionic surfactants favour micelle

formation leading to lower CMC in electrolyte solutions than in pure water.

Many physical properties change dramatically at the CMC. These changes can be exploited by determining the CMC of surfactants in CE electrolyte solutions, for example by measuring surface tension, light scattering, refractive index, electrical conductivity or electrophoretic mobility. The data are plotted against surfactant concentration, and a change in the slope corresponds to the CMC. However, the CMC obtained may differ according to the method used because micellization is a gradual aggregate growth which occurs over a finite concentration range. CMC values for the most commonly used surfactant, sodium dodecyl sulfate, in selected electrolyte solutions are listed in Table 2.

Anionic Surfactants

Anionic surfactant systems are preferred in MEKC because the electrophoretic migration of the micelles is in the opposite direction to the electroosmotic flow,

and the micelles do not interact with the negatively charged walls of the fused silica capillaries. Anionic surfactants with alkyl chain and polar group, such as sodium decyl sulfate, sodium *N*-lauroyl-*N*-methyltaurate, sodium tetradecyl sulfate, and especially sodium dodecyl sulfate (SDS) are the most widely used. Simultaneous separation of neutral and positively charged compounds is not possible at low pH because the EOF is too slow to carry the micelles to the cathode.

Most studies with anionic surfactants have been carried out under neutral or basic conditions. The most frequently used anionic surfactant, SDS, forms relatively spherical micelles with hydrophobic tail groups oriented towards the centre and charged head groups along the outer surface. The surfaces of SDS micelles possess a large net negative charge, giving them a large electrophoretic mobility toward the anode.

Another group of anionic surfactants, which has been widely used in separations of both neutral and ionic analytes, is bile salts. Bile salts have a hydroxyl-substituted steroidal backbone with hydrophilic and

hydrophobic faces and they form helical micelles. Bile salts have a lower solubilizing effect on hydrophobic compounds than does SDS.

Cationic Surfactants

Unlike anionic surfactants, positively charged surfactants, monomers and micelles are strongly attracted to the negatively charged surface of the fused-silica capillary wall and thus have a significant effect on EOF. Cationic surfactants such as long-chain alkylammonium salts may even cause a reversal of EOF through electrostatic interactions with the capillary surface, and this may occur at surfactant concentrations below the CMC. The capability for reversed EOF has been successfully exploited in MEKC separations.

Neutral and Zwitterionic Surfactants

Although neutral surfactants with zero electrophoretic mobilities cannot be exploited in the MEKC separation of nonionic solutes, they can be applied to the separation of ionic solutes. Since problems with Joule heat do not arise when nonionic surfactants are used at high concentration, large voltages can be used even when surfactants are added to the buffer in high concentration. Like the neutral surfactants, the zwitterionic surfactants do not

contribute to the net conductivity of the electrolyte solution.

Mixed Micelles

Selectivity in MEKC can often be improved by using mixed surfactants. Clearly different selectivities from those obtained with the corresponding single micelles can be achieved. Some mixed micellar systems are presented in Table 3.

High Molecular Mass Surfactants

The high molecular mass surfactants used in MEKC are either oligomers of monomeric surfactants or block copolymers with surface-active properties. It has been proposed that the micelle is formed of a single molecule, and accordingly it has been termed a 'molecular micelle'. Because their CMC values are close to zero, molecular micelles are considered to be highly stable irrespective of the experimental conditions.

Surfactants and Cyclodextrins

Cyclodextrins (CD) are the most popular chiral selectors for chiral separations by MEKC. The separation mechanism is based on differential partitioning of solutes between the micellar and CD aqueous phase.

Table 3 Selected mixed micellar systems used in MEKC

Mixed micellar system	Surfactants in the mixture ^a
Anionic–nonionic surfactants	SDS and Brij-35 SDS and Tween 60 SDBS and Brij-35 SDS and Tween 20 Bile salts and polyoxyethylene-4-dodecyl ether

Anionic–cationic surfactants	Fluorosurfactants FC 128 and FC 134
Anionic–zwitterionic surfactants	SDS and SB-12
Nonionic–nonionic surfactants	Tween 20 and Tween 80 Triton X-100 and Brij-35
Cationic–cationic surfactants	TTAC and OTAC TTAB and DTAB

^aSDS = sodium dodecylsulfate; Brij-35 = polyoxyethylene (23) dodecanol; Tween 20 = polyoxyethylene (20) sorbitane monolaurate; Tween 60 = polyoxyethylene (20) sorbitane monostearate; SDBS = sodium dodecyl benzenesulfonate; LiPFOS : lithium perfluorooctane sulfonate; LiDS = lithium dodecyl sulfate; SB-12 = *N*-dodecyl-*N,N'*-dimethyl-3-ammonio-1-propanesulfonate; TTAC = tetradecyltrimethylammonium chloride; OTAC = octyltrimethylammonium chloride; DTAB = dodecyltrimethylammonium bromide.

Most of the surfactants used in separations have been anionic.

Optimization of Separation

Resolution in MEKC is a highly complex and non-linear function of experimental variables and is very difficult to optimize systematically. In a search for the optimal conditions for separation, several mathematical models have accordingly been developed. Often just a few test runs are needed to predict the best overall running conditions, though this naturally depends on the number of parameters included in the optimization strategy. When more than one surfactant is added to the electrolyte solution, the situation is complicated by the possible micelle–micelle interactions. Examples of the statistical optimization schemes used in MEKC are listed in **Table 4**.

Detection

Of the various detection systems employed in MEKC separations, optical systems are the most extensively used, and ultraviolet detectors (UV) used in conjunction with commercial CE instruments are a typical solution.

The sensitivity of mass spectrometry (MS), and the possibility of obtaining molecular information on compounds, make the on-line coupling of MEKC with MS highly attractive. Electrospray ionization (ESI) has been one of the most popular ionization techniques in coupled CE–MS. Although MEKC is a convenient separation technique for neutral analytes, problems are encountered in the on-line MEKC–ESI–MS interface connection because the micelles in the electrolyte solution are nonvolatile and tend to contaminate the MS. A number of approaches have been developed to overcome the problems of separating neutral compounds, while at the same time preventing micelles from entering the mass spectrometer. These include use of the heart-cut technique, high molecular mass surfactants, a semipermeable membrane interface, anodically migrating micelles, and the partial filling technique. An electrospray–chemical ionization interface is a possibility for certain types of online MEKC–MS applications.

Applications

MEKC has been applied to a wide variety of compounds, including phenols and chlorinated phenols, amino acids, several pharmaceuticals and their metabolites, porphyrins, peptides, nucleic acids, nucleosides and oligonucleotides. The capability for direct injection of biological fluids (plasma, serum, urine) is a special feature of electrokinetic capillary analysis. Effective solubilization of the biological matrix components by surfactants, and increased selectivities due to hydrophobic interactions with the micellar pseudo-stationary phase are evidently advantageous in bioanalysis. The use of MEKC for therapeutic and diagnostic drug monitoring has also proven to be of considerable value.

Future Directions

The great advantage of MEKC is the feasibility to manipulate the selectivity simply by changing the composition of the micellar phase. Even though several surfactants have shown their potential to act as micellar pseudo-stationary phase, the versatility of the technique and the range of applications can be further extended by developing new synthetic micelle-forming surfactants like polyelectrolytes or exploiting mixed micelles or biomembranes as pseudo-stationary phases. Understanding the mechanisms involved will greatly facilitate the systematic optimization of the large number of experimental parameters leading to better, faster, easier, and more reliable separations. In addition, studies are still needed to clarify new possibilities to couple MEKC with mass spectrometry.

Introduction

Electrophoresis is an established separation technique, frequently used for mixtures ranging from pro-

teins and DNA to small anions and cations. However, perhaps its greatest strength lies in its remarkable ability to separate charged macromolecules. Reports describing electrophoretic separations started to appear in the 1930s, but the most significant developments really took place in the 1940s and 50s when separations with a paper or gel support matrix were used for the separation of macromolecules. The early

methods used relatively large scale apparatus, but during the later 1960s, and early 1970s, reports appeared describing separations being performed in small bore tubes filled with buffer solution. This work was extended in the early 1980s, with capillaries being a key feature of the basic methodology. This was the start of capillary electrophoresis (CE); however, it was not until the mid 1980s that great interest was shown towards a new approach to separation science. From that moment, development and commercialization came very quickly and soon there were a number of commercial instruments available for routine laboratory use.

It is not possible to cover all aspects of electrophoresis in an article such as this; indeed there are several topics that have been omitted. Fluid logic devices and freeze-melt switching are two such examples; another important area not included is the use of parallel bundles of microcapillaries that permit multiple analyses to be performed at a high throughput.

The basic element of any CE system is the separation capillary, typically 10–100 μm internal diameter and 30–100 cm long. Each end of the capillary is located in a small reservoir, which contains buffer solution and a platinum anode or cathode; typically potentials of up to 30 kV can be applied between them. Detection is achieved by a range of in-line detection methods, such as ultraviolet absorbance and other detection methods, such as mass spectrometry, can be interfaced to the capillary.

Separation is achieved due to the differing electrophoretic mobilities of the analytes in the sample, but in addition electroosmotic flow (EOF) takes place. This phenomenon gives rise to bulk flow of the solution in the capillary without the need for an external pump. For a unmodified silica capillary, the direction of flow would be from the anode to the cathode, which enables all uncharged species to be carried to the detector. This technique offers very high separation efficiencies and rapid analysis. This feature, coupled with the simplicity of the instrumentation, makes the technique ideally suited to miniaturization.

Interest in miniaturizing analytical systems is not new; indeed, the idea of a micro total analysis system (often referred to as μTAS) has been mooted for some time within the scientific community (see, for example, the paper by Martin cited in Further Reading). The ideal approach is to include sample manipulation and detection on a chip-sized device; this has given rise to the term 'lab on a chip'. Such systems employ microstructures fabricated on glass or other substrates to form integrated devices rather than attempting to construct miniaturized systems from discrete components. However, there is also consider-

able interest in the development of discrete components, such as micropumps. The conference proceedings from the recent Micro Total Analysis Systems '98 give some indication as to the diversity of the developments. While on-chip injection is feasible, some prior degree of preparation may still be necessary. For example, particulate matter would quickly block the channels, so pre-filtering would be required in such situations. Before examining in more detail electrophoresis on chips, it is important to consider the fabrication of such microchannel devices.

Fabrication of Electrophoresis Devices

There are numerous fabrication methods available, and the complexity of possible designs is virtually limitless. A popular fabrication technique is the use of photolithographic masking in conjunction with wet or chemical etching. The simplest case would be the fabrication of a single channel in a piece of glass. First, the glass would be coated with a layer of deposited metal and subsequently photoresist, e.g. by spin coating, then the pattern mask is placed on top of the photoresist. This masked surface is subsequently exposed to ultraviolet light, which transfers the pattern on to the photoresist. The unprotected area can then be removed, along with the underlying metal surface. An etching solution, such as hydrofluoric acid/nitric acid, is used to etch away the glass, forming the channel in the chip. This surface of the chip protected by the metal and photoresist layer does not etch. This process can be seen in **Figure 1**. There are a few problems with this approach; the first is that only certain materials can be etched. The second is that, as the channel is etched deeper, the width also increases. This becomes more of a problem as the depth increases, resulting in channel with nonvertical sides. This problem can also create difficulties at channel intersections, which do not have true intersecting corners due to the accelerated etching of the exposed corners.

There are many alternatives to the wet etch approach. Dry etch processes include reactive ion and laser etching; these offer a way to cut precise channels of small dimensions. Silicon is gaining in popularity as an alternative substrate to glass for chip fabrication, and by employing more than one etching technique complex devices can be produced.

In order to use polymeric materials, such as silicone rubber, or fluoropolymers for chip fabrication, new approaches are required. This may take the form of stamping, imprinting or injection moulding of the polymeric material. The approach offers a significant alternative to wet etching of channels directly,

Figure 1 The fabrication process for a separation chip fabricated from silica. The first step is to place the mask on top of the silica base plate covered in deposited metal and photoresist (step 1). After this has been exposed to UV light, the chip is developed to remove the exposed photoresist and metal. It is then etched, e.g. with hydrofluoric/nitric acids (step 2); etching does not occur where the metal and photoresist remains. The final stage (step 3) is the bonding of the cover plate on to the base plate. The two etched channels can clearly be seen.

primarily since it allows the use of a wide range of new materials, and the prospect of mass production. It requires a template to be constructed, often by wet etching or mechanical milling. This template can be considered as the negative image of the channels, and is often finally produced in a more durable material, such as nickel. From this robust template, it is pos-

sible to mass-produce thousands of channel systems with considerable speed.

All of these methods create half the chip; the next step is to attach the cover plate, i.e. the other half of the chip. It is common to locate the holes for the necessary reservoirs in this plate; the reservoirs themselves are frequently constructed by attaching cylinders, e.g. truncated pipette tips, to the top plate. For glass and silica-based systems, it is a simple step to bond the top plate on to the channels by a heating and cooling cycle (the cooling cycle is required to avoid thermally stressing the glass). The fixing of the top plate to polymeric materials can be more complex; however, perhaps the simplest method is to use a thermally activated adhesive to laminate the top plate on to the chip. Typical channel dimensions are 200 μm wide by 60 μm deep, and vary in length from 5 mm to several centimetres. Of course, many other channel dimensions can be created. Some typical patterns can be seen in Figure 2.

Theoretical Considerations

There are two important effects that need to be considered when discussing electrophoresis in microchannels; these are similar to the more conventional capillary electrophoresis. The first is electrophoretic mobility, and the second is electroosmotic flow (EOF). EOF is otherwise referred to as electroendosmotic flow.

Electrophoretic Mobility

This process forms the basis for the separation in the channel, and dictates the migration velocity of a given ion in the channel. The electrophoretic mobility (μ_e) is related to the migration velocity (v) by eqn [1], where E is the electric field strength:

$$v = \mu_e E \quad [1]$$

The units of μ_e , v and E are $\text{cm}^2 \text{V}^{-1} \text{s}^{-1}$, cm s^{-1} , and V cm^{-1} respectively. The electrophoretic mobility is proportional to the ionic charge and frictional forces. Thus, if two mobile species differ in either their charge or the frictional forces, then separation will occur. Since uncharged molecules have an electrophoretic mobility of zero, movement will not occur; this is why electrophoresis cannot separate neutral molecules. For ions of the same size, μ_e will be greater for ions with greater charge while for ions of the same charge, μ_e will be greater for smaller ions.

Electroosmotic Flow

This is a process which gives rise to the flow of buffer through the channel. It can be quite significant,

Figure 2 Some typical channel arrangements. Reservoirs A and B start and terminate the separation channel. Reservoirs C and D permit a known amount of sample to be injected into the separation channel. The reservoirs E and F permit the addition of other reagents to the separation channel.

reaching linear velocities of around 5 cm min^{-1} or greater. The rate of movement due to EOF is normally greater than the electrophoretic mobility, thus ensuring that all ionic (and uncharged) species pass the detector. However, unlike electrophoretic mobility, EOF will only occur in the presence of an electrical double layer at the surface of the channel. In **Figure 3**, an axial view of a channel etched in glass can be seen; the surface is covered in silanol groups.

When the pH of the buffer is above $\sim \text{pH } 9$, all the silanol groups are ionized. Cations from the buffer migrate towards the negative wall of the channel, and a double layer is formed. When a voltage is applied across the channel, these cations migrate towards the cathode, thereby inducing bulk flow. Electro-driven flow has a characteristically flat profile compared to the parabolic profile observed for pressure-driven systems. This significantly reduces the dispersion due to flow, and is considered to be a reason for the high efficiency separations possible. Another reason for the low dispersion observed is that the Reynolds numbers for liquids in such a system are very low, which results in limited dispersion. The electroosmotic mo-

bility (μ_{EOF}) is given in eqn [2] where η is the viscosity of the buffer, ϵ is the dielectric constant of the buffer and ζ is the zeta potential (charge on the capillary wall):

$$\mu_{\text{EOF}} = (\epsilon\zeta/\eta) \quad [2]$$

The EOF velocity can be calculated from eqn [3] which has striking similarities to eqn [1]. Here, the EOF velocity (v) is related to the electroosmotic mobility (μ_{EOF}), and the electric field gradient (E):

$$v = \mu_{\text{EOF}}E \quad [3]$$

From this, it is apparent that the overall velocity of the ionic species is the algebraic sum of the migration velocity, and the EOF velocity. By summing the two velocity terms and subsequent rearrangement of the equation, the actual velocity (v_a) of an ionic species is given by eqn [4]:

$$v_a = (\mu_E + \mu_{\text{EOF}})E \quad [4]$$

Situations do arise, such as during the analysis of anions with high electrophoretic mobility, when the

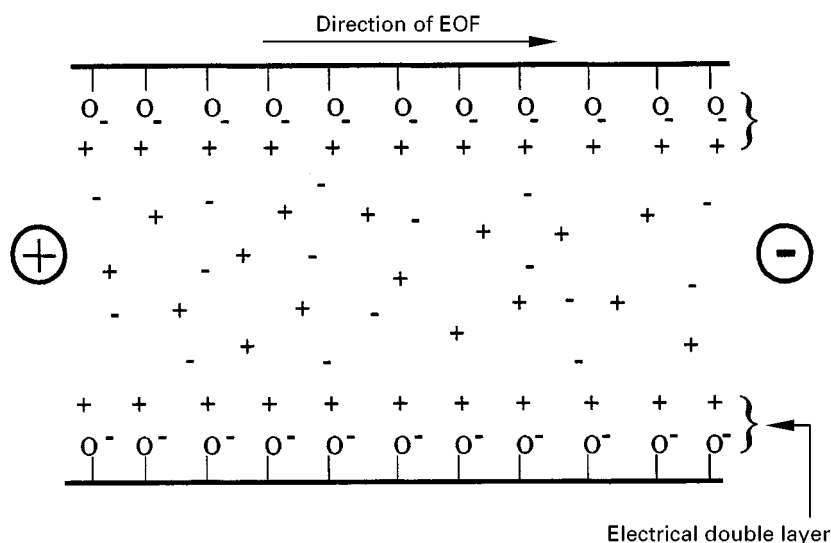

Figure 3 The double layer formed in silica channel. The layers of cations which collect along the walls of the channel will migrate towards the cathode when a voltage is applied. This gives rise to the electroosmotic flow (EOF) with the characteristic flat flow profile.

direction of EOF needs to be reversed. This can be achieved by coating the walls of the channels with a cationic surfactant. This gives an apparently positive charge to the walls, so that anions (not cations) will form the double layer. Then, when the potential is applied, EOF will be in the opposite direction. Since the influence of the double layer is generally considered to extend less than $1\text{ }\mu\text{m}$ into the solution, overlap of the double layer should not be an issue for channels of greater than $5\text{ }\mu\text{m}$ minimum dimension. However, for channels of smaller dimension, the flat flow profile model may no longer be valid, and great care should be exercised in describing the flow.

To prevent EOF completely, the walls of the channel need to be rendered neutral. In silica channels, this ought to be achievable by coating the walls with a compound such as trimethylchlorosilane, to end-cap all terminal silanol groups. However, in practice, it is impossible to eliminate all EOF since residual surface charge remains. Since many microsystems are now being constructed from polymeric substrates, EOF normally does not occur to any appreciable extent. This is due to the absence of ionizable or charged surface groups. In this situation, EOF could be induced by coating the walls of the channel with a charged compound, such as cetyltrimethylammonium bromide.

Practical Considerations

Perhaps the key practical consideration is whether integrated on-chip detection will be employed, or whether the separated compounds will be transferred to another device, such as a mass spectrometer. In

a similar context to conventional capillary electrophoresis separations, on-chip detection is the ideal option, since it minimizes dispersion and the dead volume associated with the transfer of analytes from the chip to a detector. The dead volume will normally be far in excess of the separation volume, thus band broadening will be a serious problem.

The other key issue is sample introduction. The simplest system relies on the EOF to introduce the sample into the separation capillary. Consider the channel arrangement in **Figure 4**. The channels are etched into silica, and no deactivating treatment is applied. Under normal conditions (I), the applied voltage between reservoirs A and B induces EOF. In addition, the potential field gradient will give rise to electrophoretic separations.

Since only buffer is flowing, this does not give rise to any apparent separation effect. When the voltage is manipulated such that it is now between reservoirs C and D (II), EOF is induced between the reservoirs, thus the sample is introduced, and occupies a small section of the main channel. Once the voltage is restored between A and B, the separation step begins (III). Here, the sample is moved by the EOF towards reservoir D, and separation occurs due to electrophoretic mobility.

In situations where EOF is insignificant due to the absence of surface charge, the injection step relies either on the electrophoretic movement of the analytes or an applied pressure. There is, of course, a potential problem with electrophoretic mobility, and that is the discriminatory effects observed between analytes of high and low electrophoretic mobility. Pressure, on the other hand, offers a simple

Figure 4 Sample introduction into the separation channel. (I) When the voltage is applied between reservoirs A and B, the separation channel is filled with running buffer. (II) To inject a sample, the voltage is applied between C and D: the sample moves into a short section of the separation channel. (III) With the voltage restored across A and B, the sample moves along the separation capillary, and separation occurs.

and nondiscriminatory route for sample introduction. This can be achieved by either applying pressure to one reservoir in order to force the analyte through the system, or by deformation of the chip (in situations where the polymer is flexible). In either case, a valveless injection method is used; this greatly simplifies the operational aspect of these systems.

Applications

In this section, several types of application will be considered. While much of the discussion will be related to the separation of compounds on chips using electrophoresis, it is impossible to neglect the potential of EOF alone for fluid mobility, which is unaffected by back-pressure.

Electrophoretic Separations

Much of the literature available on chip-based electrophoretic separations features capillary zone elec-

trophoretic (CZE) separations; however, there are many other types of separation possible, such as isotachopheresis and electrokinetic focusing.

Perhaps the simplest applications are based on CZE within silica microchannels. Here EOF and electrophoretic mobility can be utilized, the EOF for injection and bulk flow of solutions through the capillary, and electrophoretic mobility for the actual separation process. A typical separation capillary would be 50 mm long, 45 μm wide and 8 μm in depth, with an applied potential in the range 600–1200 V along the 50 mm length. The types of samples that can be separated by this technique are extensive (not surprising, given the diversity of the applications for conventional CZE) but include small anions and cations, monoclonal antibodies, theophylline and DNA fragments. There are a number of potential detectors, but those based on optical or electrochemical methods are the most frequently used.

Electrochemical detection can easily be incorporated on to a microchip, but requires the detector to be located after the high voltage section of the channel. This is necessary to prevent the high voltage causing interference with the detection. This can be achieved in such a system as described above, by locating the electrochemical detector in the channel just after the ground electrode. The EOF occurring in the channel would pump the fluid along the channel from the ground electrode to the detector electrodes. Over this short region, band broadening should not pose a significant problem. It is similar in principle to the porous junction technique widely used in conventional CE. It is possible to achieve limits of detection of micromolar levels or better with electrochemical detection.

Spectroscopic methods fall into two main classes – absorbance and fluorescence. Absorbance measurements are simple to effect, but commonly suffer from relatively low sensitivity. This is primarily due to the channel dimensions resulting in a very small path length. Measurements across a 50 μm channel would give rise to a very small absorbance, since absorbance is proportional to path length. It is possible to increase the path length (Figure 5), but absorbance measurements do not have the sensitivity of fluorescence measurements, although they are generally applicable to a wider range of analytes. In addition, for practical reasons, dual-channel systems are not easily set up and this can lead to instability in the detector signal.

Fluorescence measurements can provide limits of detection in the picomolar range (varying from around 2 pmol L^{-1} upwards), and have even been reported for counting single chromophore molecules. Generally, the excitation source is directed along the

to an electrophoretic separation chip is one possible answer. However, there is no reason why reactions cannot be carried out on such devices. Since it does not require the investment of a large chemical plant, the reactions can be performed where required, thus reducing the need to transport hazardous chemicals across countries. Since many reactors can be constructed on a single chip, and many chips located in the same area, it is evident that this technology will provide hazardous or chemically unstable chemicals where they are required.

Electrophoresis is a separation technique that is normally performed in an aqueous environment. This is due to the fact that the separation mechanism is based on the difference in migration rate of charged species in an electric field. Species (ions/molecules or particles) with a difference in their charge over size ratio will exhibit a difference in migration rate. Most charged species are fairly soluble in aqueous media and thus water is the most obvious solvent for electrophoresis. However, in a number of nonaqueous solvent systems, it is possible to obtain sufficient conductivity to perform electrophoresis. If such systems are utilized with the technique of capillary electrophoresis, a number of advantages compared to aqueous systems are obtained in the separation of small molecules. Nonaqueous electrophoresis of biopolymers like polysaccharides, nucleic acids and proteins is not of practical use due to lack of solubility of such molecules in organic solvents.

Nonaqueous Capillary Electrophoresis

Only a few attempts to perform nonaqueous paper electrophoresis have been described and these articles

were reviewed in 1978. In 1984 nonaqueous capillary electrophoresis (NACE) was briefly mentioned in a single publication, but not utilized further. However, since 1993 the use of nonaqueous media for capillary electrophoresis has seen renewed interest in the separation of drug substances due to the high separation selectivity obtained in these systems.

The electrophoretic migration of the solutes is influenced by the nature of the solvent or solvent mixture used for the electrophoresis medium in three main ways:

1. The mobility may change due to changes in the size of the solvated ion.
2. The dielectric constant of the organic solvent may influence the equilibrium of the protolytic dissociation. The higher the value of the dielectric constant, the higher the degree of ionization of acids and bases.
3. The acid–base property of the solute, expressed by its pK_a value, may change due to the differentiating effect of many organic solvents.

The latter effect of the three is the most significant, as the dissociation constant, K_a , may change many orders of magnitude for different solvents.

The increased selectivity of separation in organic solvents compared to aqueous systems is due to the fact that the levelling effect of water is eliminated. If

Table 1 Classification of organic solvents according to their Brønsted acid–base behaviour

Solvent designation		Relative acidity	Relative basicity	Examples
Amphiprotic	Neutral	+	+	<i>MeOH</i> , glycerol, phenol, <i>tert</i> , butyl alcohol
	Protogenic	+	—	Sulfonic acid, formic acid, <i>acetic acid</i>
	Protophilic	—	+	Liquid ammonia, <i>FA</i> , <i>NMF</i>
	Dipolar protophilic	—	+	<i>DMSO</i> , <i>DMF</i> , tetrahydrofuran, 1,4-dioxan, pyridine
Aprotic	Dipolar protophobic	—	—	<i>MeCN</i> , acetone, nitrobenzene, sulfolane, <i>PC</i>
	Inert	—	—	Aliphatic hydrocarbons, benzene, 1,2-dichloroethane, tetrachloromethane

— indicates weaker and + indicates stronger acid or base than water. DMF, *N,N*-dimethylformamide; DMSO, dimethyl sulfoxide; FA, formamide; MeCN, acetonitrile; MeOH, methanol; NMF, *N*-methylformamide; PC, propylene carbonate. Solvents *in italic* are the ones that are preferred for NACE. Reproduced with permission from Tjørnelund J and Hansen SH (1999) *Journal of Biochemistry and Biophysical Methods* 38: 139–153.

strong acids or bases are dissolved in water, they all show up with about the same acid or base strength. If the same acids or bases are dissolved in organic solvents they will exhibit very different protolytic behaviour depending on the degree of dissociation, which again depends on the solvent in question.

Important factors influencing the choice of organic solvent or solvent mixture for a given separation are volatility, the dissolving power towards suitable electrolytes, viscosity and dielectric constant, UV transparency and, last but not least, the effect on the separation selectivity of the system. Information on the viscosity and volatility, the auto protolysis constant, the dielectric constant at standard conditions and the UV transparency of the neat solvents may be found in the literature. In contrast, data on solvent mixtures and systematic studies of how to choose solvents and electrolytes in order to control the selectivity of the electrophoretic system are limited

and thus the choice of separation media is still a matter of trial and error. Solvents may be classified according to their Brønsted acid–base behaviour; a simplified version of this classification is shown in Table 1.

Practical Considerations

Choice of Organic Solvent

The physical chemical properties of the organic solvents preferred for NACE are given in Table 2 and, as mentioned above, the physical constants have a major impact on the choice of solvent or solvent mixture for a given electrophoretic separation. Some of the more practical considerations are the chemical resistance of parts in the CE instrument towards the solvent, the volatility of the solvent, the solvating power of the solvent towards electrolytes, the UV transparency and the viscosity of the solvent.

Table 2 Physicochemical parameters of selected solvents

Solvent	Viscosity, η (cP)	Dielectric constant, ϵ	ϵ/η	pK_{auto}	T_{boil} ($^{\circ}\text{C}$)	UV cutoff (nm) (1 cm cuvette)
Water	0.89	78.4	89.9	14	100	<200
FA	3.3	111	33.6	16.8	210	275
NMF	1.65	182	110.3	10.7	182	275
DMF	0.8	36.7	45.9	29.4	153	260
DMSO	1.99	46.7	23.4	33.3	189	260
MeOH	0.544	32.7	60.6	17.2	65	205
PC	2.5	64.4	25.7	Not detected	242	200–230
MeCN	0.34	37.5	110.3	Not detected	82	200–230
Glycerol	945	42.5	0.045	—	290	205
Acetic acid	1.04 ₃₀	6.152	5.91	14.45	118	—

All values are at 25°C unless otherwise stated in subscript. For abbreviations, see Table 1. Reproduced with permission from Tjørnelund J and Hansen SH (1999) *Journal of Biochemistry and Biophysical Methods* 38: 139–153.

Apparatus: Quanta 4000. Conditions: 64 cm (56 cm to the detector) \times 75 μm i.d. capillary, hydrostatic (10 cm) injection for 15 s, ambient (27–30°C), 20 kV (62 μA) and UV detection at 214 nm. (C) 25 mmol L⁻¹ ammonium acetate and 1 mol L⁻¹ acetic acid in acetonitrile. Apparatus: HP3DCE instrument. Conditions: 64 cm (55.5 cm to the detector) \times 50 μm i.d. capillary, injection of 3 s at 5 kPa (50 mbar), 25°C, 25 kV (7 μA) and UV detection at 214 nm. Adapted with permission from Bjørnsdottir I, Tjørnelund J and Hansen SH (1996) Selectivity enhancement in capillary electrophoresis using nonaqueous media. *Journal of Capillary Electrophoresis* 3: 83–87.

Solvents with a high vapour pressure and thus a high volatility (e.g. methanol (MeOH) and acetonitrile (MeCN)) may be inconvenient for automated analysis in some instruments due to problems with evaporation of the electrophoresis medium from the

run buffer vials as well from the sample vials. In CE the detection is often performed by measuring the UV absorbance of the analyte at a relatively short wavelength (e.g. at 214 nm or below) in order to increase the sensitivity. However, many organic sol-

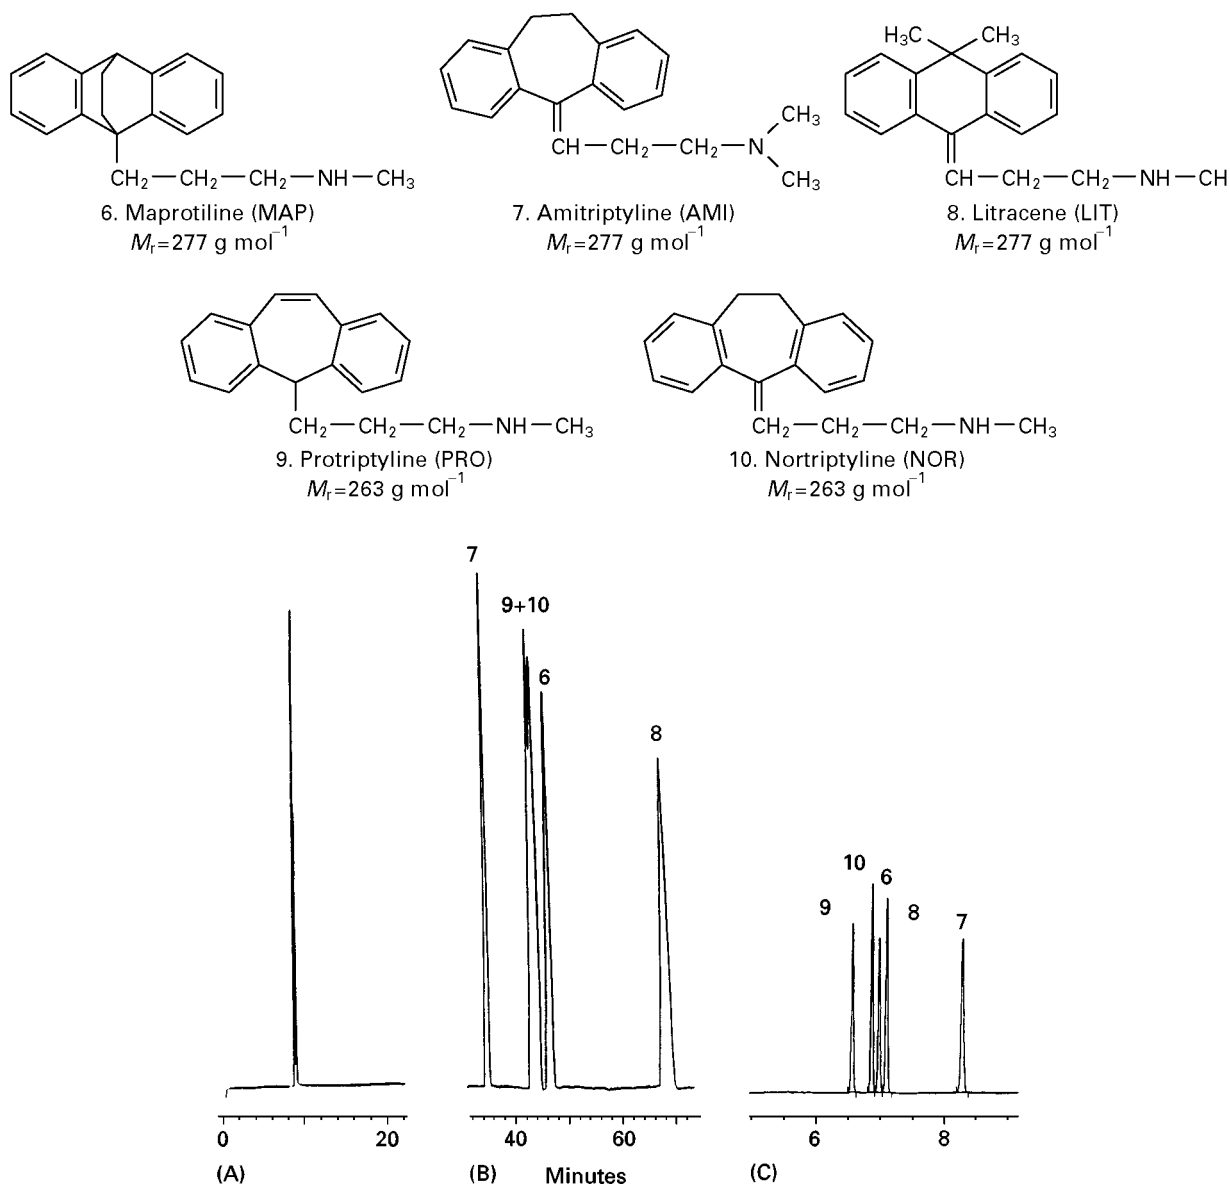

Figure 2 Electropherograms of five basic drugs with equal or very similar mass over charge ratio. (C) 25 mmol L⁻¹ ammonium acetate and 100 mmol L⁻¹ sodium acetate in methanol + acetonitrile (1 : 1 v/v) and 25 kV (23 μ A). Apparatus and other conditions as in Figure 1C. Adapted with permission from Bjørnsdottir I, Tjørnelund J and Hansen SH (1996) Selectivity enhancement in capillary electrophoresis using nonaqueous media. *Journal of Capillary Electrophoresis* 3: 83–87.

vents have a UV cutoff at 214 nm or above (Table 2). Nevertheless, solvents like MeCN and MeOH may be used for measurements performed at a wavelength as low as 200 nm as the light path through the capillary is very short compared to the 1 cm cuvette used for the determination of the UV cutoff wavelength. The amides and dimethylsulfoxide can only be used when detection at wavelengths above *c.* 245 nm is sufficient of the application.

On the positive side, organic solvents often intensify the fluorescence relative to what is observed for

given solutes in aqueous media. This has been used to decrease detection limits in NACE for analysis of tetracyclines in biological matrices.

Choice of Electrolyte

The choice of electrolyte is important and will influence the separation. However, due to the low solubility of many electrolytes in organic solvents, it can be difficult to find a suitable electrolyte. The more polar solvents, like MeOH, DMSO, formamide, *N*-methylformamide and *N,N*-dimethylformamide, possess

a good solvating power towards the electrolytes commonly used in NACE. So far, ammonium acetate has been the most frequently used electrolyte in NACE systems and acetic acid or sodium acetate have often been used in combination with ammonium acetate in order to adjust the acid–base properties of the electrophoresis medium. Quaternary ammonium salts have also been used a number of times with success, e.g. in the separation of phenols and carboxylic acids. More rarely, Tris, magnesium acetate, citric acid, formic acid, trifluoroacetic acid and methanesulfonic acid have been used.

When coupling CE to mass spectrometry (MS), it is an advantage to choose a volatile electrolyte, e.g. ammonium acetate, in order to limit background noise or cluster ion formation.

Other Additives

A number of polyalcohols and surfactants such as the Tweens® have been used as additives. Their primary function is to decrease the electroosmotic flow (EOF) and thus prolong the time for electrophoretic separation.

Also chiral separations are possible in NACE using either cyclodextrines or chiral counter ions as additives.

Reversal of EOF

The separation of anionic solutes in CE may lead to extended time of analysis due to their migration in the direction opposite to EOF. One method of decreasing the analysis time is to reverse the EOF, thus making the anions migrate in the same direction as the EOF. In aqueous CE, the addition of long alkyl chain trimethylammonium ions is used for this purpose, e.g. in the analysis of inorganic anions and phenols. This principle may also be used in NACE. However, the long alkyl chain trimethylammonium ions are not able to form hemimicelles at the inner capillary surface when using nonaqueous solvents and thus the EOF is not reversed. Addition of the polycation hexadimethrine bromide to the nonaqueous electrophoresis medium may result in suitable and stable systems with reversed EOF, even when used at fairly low concentrations (0.001–0.05%).

Applicability of NACE

In CE the separation of solutes is due to differences in the charge over size ratios and thus very similar substances may be difficult to separate in aqueous CE unless special mechanisms like micellar electrokinetic chromatography (MEKC) are involved. Of course this involves addition of one or more surfactants.

Figure 3 Electropherograms of *cis-trans*- and diastereo-isomers. (A) Separation of *cis*- and *trans*-flupenthixol decanoate using 50 mmol L⁻¹ ammonium acetate and 1 mol L⁻¹ acetic acid in methanol + acetonitrile (1 : 1, v/v), above: *cis*-flupenthixol decanoate with 0.5% *trans*-isomer added; below: *trans*-flupenthixol decanoate. Conditions: 64 cm (55.5 cm to the detector) × 50 μm i.d. capillary, injection for 3 s at 5 kPa (50 mbar), 25°C, 30 kV (9 μA) and UV detection at 230 nm. Test solution: 5.0 mg mL⁻¹ of the sample in methanol + acetonitrile (1 : 1 v/v). Peak identity: 1, *cis*-flupenthixol decanoate; 2, *trans*-flupenthixol decanoate; U, unknown. Table 3 Applications of NACE in analysis of food, pharmaceuticals and biological fluids

<i>Solvents</i>	<i>Electrolytes</i>	<i>Analytes</i>
<i>Applications within food</i>		
NMF-dioxane (1 : 1 v/v)	40 mmol L ⁻¹ Tris, 2.5 mmol L ⁻¹ anthraquinone-2-carboxylic acid	Free saturated long chain fatty acids (<i>n</i> -C ₁₄ - <i>n</i> -C ₂₆). Separation of dimeric and trimeric acids and hydrogenated fish oil
NMF	500 mmol L ⁻¹ magnesium acetate tetrahydrate	Tetracycline (TC), oxytetracycline (OTC), chlorotetracycline (CTC), demeclocycline, 4-epitetracycline, anhydrotetracycline, 4-epianhydrotetracycline, and desmethyltetracycline
Propylene carbonate	Tetraalkylammonium ions, long chain trimethylammonium ions 20 mmol L ⁻¹ tetradecylammonium bromide (vitamin K ₁ and preservatives)	TC, OTC and CTC in milk and plasma Phenanthrene, β -naphthol, preservatives: methylparaben, ethylparaben and propylparaben, thiourea (EOF marker) and vitamin K ₁
<i>Applications within pharmaceuticals</i>		
10–100% MeOH	Ammonium acetate, acetic acid	Haloperidol and synthetic putative metabolites, pyrazoloacridine and mifentidine
Mixture of MeOH and H ₂ O	Ammonium acetate, acetic acid	Haloperidol, cimetropium and mifentidine
MeOH	5 mmol L ⁻¹ ammonium acetate, 100 mmol L ⁻¹ acetic acid	Haloperidol and its synthetic putative metabolites, pyrazoloacridine and its synthetic putative metabolites, mifentidine and its synthetic putative metabolites
MeOH and mixture of MeOH and MeCN	Ammonium acetate, tetrabutylammonium bromide, tetrabutylammonium hydrogen sulfate and tetrapentylammonium bromide	Tamoxifen and four phase I metabolites
MeOH, MeCN, mixture of MeOH and MeCN, formamide, NMF, DMF, DMA, DMSO	25 mmol L ⁻¹ ammonium acetate, 0–1 mol L ⁻¹ acetic acid or 100 mmol L ⁻¹ sodium acetate Application: 25 mmol L ⁻¹ ammonium acetate, 1 mol L ⁻¹ acetic acid in MeCN	Imipramine, di-desmethylinipramine, desmethylinipramine, methylimipramine and imipramine- <i>N</i> -oxide. Maprotiline, amitriptyline, litracene, protriptyline and nortriptyline. Application: imipramine <i>N</i> -oxide and impurities
MeOH : MeCN : DMF (45 : 49 : 6 v/v/v)	25 mmol L ⁻¹ ammonium acetate, 10 mmol L ⁻¹ citric acid and 118 mmol L ⁻¹ methanesulfonic acid	Tetracycline and three degradation products. Tetracycline, oxytetracycline, doxycycline, desmethyltetracycline and chlortetracycline
MeOH : MeCN (1 : 1 v/v)	20 mmol L ⁻¹ ammonium acetate, 1 mol L ⁻¹ acetic acid	Morphine analogues, antihistamines, antipsychotics and stimulants
Formamide, NMF or DMF	Citric acid or acetic acid mixed with Tris. Chiral selectors: β -CD, γ -CD and derivatized β -CD. Addition of long chain alkyl ammonium salts investigated	Racemic mixtures of chlorphedianol, chlorcyclizine, ethopropazine, mianserin, nefopam, primaquine, propiomezine, trihexyphenidyl, trimeprazine, trimipramine and thioridazine
NMF, formamide and mixtures of both	25–200 mmol L ⁻¹ β -CD, 10 mmol L ⁻¹ NaCl	Dansylated amino acids
NMF	5–100 mmol L ⁻¹ β -CD and 10 mmol L ⁻¹ NaCl	Dansylated amino acids
MeOH	Ammonium acetate, acetic acid, quinine	<i>N</i> -3,5-dinitrobenzylated amino acids, (±)-1,1'-binaphthyl-2,2'-diyl hydrogen phosphate and <i>N</i> -[1-(1-naphthyl)ethyl]phthalomic acid
MeCN	(±)-Camphorsulfonic acid potassium or sodium salt, 1 mol L ⁻¹ acetic acid 0.2 mol L ⁻¹ Tween 20	Atenolol, bisoprolol, bunitrolol, metoprolol, pindolol, propranolol, salbutamol, ephedrine, epinephrine, cisapride and synthetic impurities
Formamide	Tetra- <i>n</i> -butylammonium perchlorate. Chiral selector: (+)-18-crown-6-tetracarboxylic acid	1-Naphthylethylamine, 1-phenylethylamine, phenylalanine, DOPA, tryptophan, norephedrine, noradrenaline and 2-amino-1,2-diphenylethanol

Table 3 *Continued*

<i>Solvents</i>	<i>Electrolytes</i>	<i>Analytes</i>
Formamide, NMF, DMF, DMA, DMSO, MeOH, MeCN and mixtures of MeOH and MeCN	25 mmol L ⁻¹ ammonium acetate, 1 mol L ⁻¹ acetic acid	Morphine, codeine, normorphine, thebaine, noscapine and papaverine. Application: morphine in opium tincture
MeOH : MeCN (75 : 25)	25 mmol L ⁻¹ ammonium acetate, 1 mol L ⁻¹ acetic acid	Morphine
NMF	500 mmol L ⁻¹ magnesium acetate tetrahydrate	Oxytetracycline in an ointment
Mixtures of MeOH and MeCN	Ammonium acetate, ammonium chloride, acetic acid, trifluoroacetic acid, formic acid, methane sulfonic acid	<i>Cis-trans (Z-E)</i> isomers of chlorprothixene, thiothixene, clopenthixol, flupenthixol, flupenthixol decanoate, clomiphene and diastereomers: L-Ala-L-Phe, L-Ala-D-Phe; quinine, quinidine, cinchonine and cinchonidine
Mixtures of MeOH and MeCN	Sodium acetate	A range of penicillins, cephalosporins and nonsteroidal anti-inflammatory drugs
MeOH	20 mmol L ⁻¹ CAPS and 0–40 mmol L ⁻¹ Brij 35	Mesoporphyrin, coporphyrin, pentaporphyrin, hexacarboxylporphyrin, heptacarboxylporphyrin and uroporphyrin
<i>Applications within biological fluids</i>		
10–100% MeOH in H ₂ O	20 mmol L ⁻¹ ammonium acetate, 1% acetic acid	Pyrazoloacridine, two metabolites and a synthetic degradation product in urine
NMF	500 mmol L ⁻¹ magnesium acetate tetrahydrate	Tetracycline (TC), oxytetracycline (OTC), chlortetracycline (CTC), demeclocycline, 4-epitetracycline, anhydrotetracycline, 4-epianhydrotetracycline and desmethyltetracycline. TC, OTC and CTC in cow milk and human plasma
MeOH	5 mmol L ⁻¹ ammonium acetate, 100 mmol L ⁻¹ acetic acid	Mifentidine and three metabolites in rat liver homogenate
MeOH : MeCN (1 : 1 v/v)	50 mmol L ⁻¹ ammonium acetate, 159 mmol L ⁻¹ sodium acetate and 0.002% (w/v) hexadimethrine bromide	Acetylsalicylic acid and three metabolites: salicylic acid, salicyluric acid and gentisic acid in plasma and urine

NACE provides high separation power of very similar substances without using additives like surfactants or cyclodextrins. In **Figures 1** and **2** the separation of very similar substances using NACE are compared to separation in an aqueous CE and a MEKC system. As seen in **Figure 2**, even substances expected to have identical mass over charge may be separated in a short time compared to the aqueous systems. **Figure 3** shows the separation of *cis-trans* isomers and diastereoisomers. These isomers are also expected to have the same mass over charge ratio. The use of NACE in the analysis of food, pharmaceuticals and biological fluids has been reviewed by Bjørnsdottir and co-workers and in **Table 3** an overview of applications is given. An important practical consequence of using a NACE separation medium is that the organic phases resulting from either simple extractions or from eluents from solid-phase extractions can be injected directly into the system, thereby saving time.

Furthermore, some NA solvents seem promising for CE-MS experiments due to the volatility of the solvents and the relatively low current generated in the organic solvents. The low current is comparable to the current generated in electrospray MS interfaces and therefore the stability of online CE-MS is optimized.

Two questions are often raised in connection with practical work with NACE. How important is it that the electrophoresis medium is really nonaqueous? This is not crucial. A content of water up to 1% will not influence the separation efficiency and selectivity significantly. Is it possible to perform quantitative analysis using NACE? Yes, if steps against evaporation are taken when volatile solvent are used, the reliability of the methods is comparable to that of aqueous systems (**Table 4**). A number of applications including validated quantitative methods are given in **Table 4**.

Table 4 Validation data from quantitative NACE analysis of food, pharmaceuticals and biological fluids

Analytes	Linearity (r^2)	Repeatability of inj. (%RSD)	LOD	Accuracy
Free saturated long chain fatty acids ($n\text{-C}_{14}\text{-}n\text{-C}_{26}$)	0.994 ($n_{16}\text{-}n_{20}$) 0.985 ($n_{22}\text{-}n_{26}$)	Inter-day: 2.1–39% ($n = 6$) at three concentration levels	0.025 mmol L ⁻¹	nd
Tetracyclines in plasma and milk	0.999	Inter-day repeatability of the method: 3.6–10.2% ($n = 6$) at three concentration levels	25 ng mL ⁻¹ of TC, OTC or CTC	97.2% Oxytetracycline ($n = 6$, %RSD = 4.2%) and 63.3% ($n = 6$, %RSD = 3.6%) at two conc. in milk
Vitamin K ₁ , propylparaben and methylparaben	0.993	~ 3% ($n = 6$) at three concentration levels for all three analytes	nd	98% Vitamin K ₁ ($n = 6$, %RSD = 4.95%) 96% Propylparaben ($n = 6$, %RSD = 4.45%) 82% Methylparaben ($n = 6$, %RSD = 2.26%)
Tetracycline and three degradation products	0.993–0.998	Inter-day: 3.4–13% (five concentration levels)	nd	nd
Oxytetracycline in an ointment	> 0.999	Inter-day: 2.8–4.4% for peak area ($n = 6$) at three conc. levels. For migration time: > 0.8% within day ($n = 8$) and < 3.3% in-between days ($n = 6$)	nd	96.1–97.3% Oxytetracycline at three concentration levels ($n = 6$)
Morphine in pharmaceutical products	> 0.999	Inter-day: 2.0% ($n = 6$)	0.2 µg mL ⁻¹	100.7–101.2% (three concentrations)
Acetylsalicylic acid and three metabolites: salicylic acid, salicyluric acid and gentisic acid in plasma and urine	Good in the range: 5–500 µg mL ⁻¹	Inter-day: plasma: 0.8–5.0% ($n = 6$), urine: 1.0–5.4% ($n = 6$) at three conc. levels	LOQ : 5 µg mL ⁻¹ in plasma and 25 µg mL ⁻¹ in urine	Plasma: 65–99%, urine: 75–97%

nd, not determined; LOQ, limit of quantitation. Reproduced with permission from Bjørnsdottir *et al.* (1998) *Electrophoresis* 19: 2179.

Concluding Remarks

The primary advantages of using nonaqueous media for CE may be outlined in four statements:

1. The separation selectivity is improved by using neat organic solvents and the selectivity can easily be altered by changing the nature of the organic solvent or using mixtures of organic solvents.
2. Analysis of hydrophobic compounds is facilitated as their solubility is higher in organic solvents than in aqueous media.
3. Sample preparation is facilitated as extracts obtained with organic solvents may be injected directly into the nonaqueous system (e.g. the eluate from a solid-phase extraction cartridge, when using MeOH or MeCN as the eluent, may be used for CE without further treatment).
4. The relatively low current generated in organic solvents combined with the volatility of the solvents seems to be promising for CE-MS experiments.

Nuclear Magnetic Resonance Detection in Capillary Electrophoresis

See II/ELECTROPHORESIS/Capillary Electrophoresis-Nuclear Magnetic Resonance

One-dimensional Polyacrylamide Gel Electrophoresis

P. G. Righetti, University of Verona, Verona, Italy

Copyright © 2000 Academic Press

Electrophoresis is based on the differential migration of electrically charged particles in an electric field. As such, the method is applicable only to ionic or ionogenic materials, i.e. substances convertible to ionic species (a classic example being neutral sugars, which form negatively charged complexes with borate). In fact, with the advent of capillary zone electrophoresis (CZE) it has been found that a host of neutral substances can be induced to migrate in an electric field by inclusion in charged micelles, e.g. of anionic (sodium dodecyl sulfate, SDS) or cationic (cetyltrimethylammonium bromide, CTAB) surfactants. Even compounds that are not ionic, ionogenic, or complexable can often be analysed by CZE as they are transported past the detector by the strong electroosmotic flow on the capillary walls.

Basically, if one plots the velocity of a zone against the pH in the same zone, electrophoretic techniques can be divided into four main types: zone electrophoresis (ZE) together with moving-boundary electrophoresis (MBE), discontinuous (disc) electrophoresis, isotachopheresis (ITP) and isoelectric focusing (IEF). **Figure 1** represents this classification. It can be seen that IEF and ITP are based on principles that are 'perpendicular' to ZE and MBE. In particular, in IEF, once steady-state conditions have been attained, all proteins reach a zero-velocity ($v = 0$, pH-axis). It is then clear that ITP closes the ring of possibilities: all zones move with the same velocity, but at different pH. Alternatively, electrophoretic techniques may be enumerated in chronological order, as follows: moving boundary electrophoresis (MBE), zone electrophoresis (ZE), disc electrophoresis, isoelectric focusing (IEF), sodium dodecyl sulfate/polyacrylamide gel electrophoresis (SDS-PAGE), two-dimensional (2-D) maps, isotachopheresis (ITP), staining techniques, immobilized pH gradients (IPG), and capillary zone electrophoresis.

ZE became a reality when hydrophilic gels (acting as an anticonvective support) were discovered. Grabar and Williams in 1953 first proposed the use of an agar matrix (currently abandoned in favour of a highly purified agar fraction, agarose). They also combined, for the first time, electrophoresis on a hydrophilic support with biospecific detection (immunoelectrophoresis). Barely two years after that, Smithies (1955) applied another gel, potato starch. The starch blocks were highly concentrated matrices (12–14% solids) and subsequently introduced a new parameter in electrophoretic separations: molecular sieving. Human sera, which in cellulose acetate or paper electrophoresis, were resolved in barely five bands, now produced a spectrum of 15 zones. The most important discovery, however, came with the introduction of polyacrylamide gels and disc electrophoresis; this discovery was thoroughly debated in

Figure 1 Classification of the four modes of electrokinetic techniques. The velocity of a zone is plotted against the pH in the same zone. (A) zone and moving boundary electrophoresis; (B) discontinuous electrophoresis; (C) isoelectric focusing; (D) isotachopheresis. a classic electrophoretic volume, which appeared in December, 1964 in the *Annals of the New York Academy of Sciences* (a collectors item!). This was like the explosion of a supernova in the firmament of electrokinetic methodologies. Although most of the above-mentioned techniques belong to the category of one-dimensional PAGE, we will only mention three of them here in detail: disc electrophoresis, SDS electrophoresis and pore-gradient-gel electrophoresis. The other techniques such as IEF and ITP, being steady-state methods, are best performed in non-sieving media. The technique of moving-boundary electrophoresis died out long ago.

Discontinuous Electrophoresis

In 1959 Raymond and Weintraub described the use of polyacrylamide gels (PAG) in ZE, which offered UV and visible transparency (starch gels are opalescent) and the ability to sieve macromolecules over a wide range of sizes. **Figure 2** gives a scheme of reaction for producing polyacrylamide gels from the standard mixture of monomers, acrylamide and the cross-linker Bis. It should be noted that although this matrix should be neutral (except where accidental hydrolysis of acrylamide to acrylic acid occurs), in reality it is not completely devoid of charges; at the

Figure 2 The polymerization reaction of acrylamide. The chemical formula of acrylamide, *N,N'*-methylenebisacrylamide (Bis) and of the initiators (peroxysulfate and *N,N,N',N'*-tetramethylethylenediamine, TEMED) are shown. On the right-hand side, growing polyacrylamide chains, in equilibrium with free monomers, are illustrated. In this particular case, it is assumed that the chain termini are TEMED molecules, although peryoxysulfate could be just as well incorporated.

chain termini either initiator, N,N,N',N' -tetramethylethylenediamine (TEMED), or sulfate, could be incorporated which would impart positive or negative charges, respectively. The fact that polyacrylamides always exhibit a residual electroosmotic flow towards the cathode suggest that an excess of negative charges is incorporated over positive ones (TEMED).

In 1964, Ornstein and Davis created discontinuous (disc) electrophoresis by applying to PAG a series of discontinuities (of leading and terminating ions, pH, conductivity, and porosity), thus further increasing the resolving power of the technique. In discontinuous disc electrophoresis (the principle of which is outlined in Figure 3), the proteins are separated on the basis of two parameters: surface charge and molecular mass. The matrix is divided into three sections (from bottom up): a 'separation', or 'running' gel, a 'spacer' or 'stacking' gel, and a sample gel. A sharp discontinuity exists at the running/stacking interface: the bottom gel is a tightly knit sieve (with small pores), while the second and third layers are minimally sieving, open-pore structures. At the same interface, a second discontinuity exists in pH. In fact, the running gel is titrated at pH 8.9, whereas spacer and sample gels are buffered at pH 6.7. This gel region at

pH 6.7 is also a low conductivity region (third discontinuity), which means that a voltage gradient will be generated in this zone when an electric current is passed through it. Below and above it (in the cathodic chamber) high-conductivity regions are found. A fourth discontinuity exists at the interface between the upper gel end and the liquid in the cathodic compartment: below it only Cl^- (leading, L) ions are present, while above it only glycinate (trailing or terminating, T) ions are found.

Why is there the need for such a complicated system? This intricate set up must satisfy the Kohlrausch regulating function, which is at the heart of ITP (in fact, movement of ions in the first two gel segments will be according to ITP rules). If all the ions in the system are arranged in such a way that $\mu_L > \mu_P > \mu_T$ (where μ is the mobility of leading, protein and terminating ions, respectively), then, upon playing a voltage gradient, they will migrate down the gel cylinder with equal velocities and the boundary between each adjacent species will be maintained. As soon as the electric circuit is closed, Cl^- (fastest moving) ions are swept down the column towards the anode. Just behind this boundary, all protein ions will start arranging themselves in order of their mobilities, with the lowest pI component next to the Cl^- boundary and

Figure 3 Principle of discontinuous disc electrophoresis. (A) Sample in sample gel; (B) sample concentration in stacking gel; (C) sample separation in running gel. From top to bottom, the following phases are encountered: glycine buffer at pH 8.3 in the cathodic reservoir; sample gel and spacer gel, both titrated to pH 6.7; small-pore running gel, titrated to pH 8.9; and glycinate buffer again in the anodic reservoir at the bottom. In part (C) it is seen that, as the glycinate boundary sweeps down the gel past the protein zones, the pH increases from 8.9 (in A and B) up to 9.5. (Reproduced with permission from Ornstein, 1964.)

the highest pI species closing the procession. The last 'wagon of the train' is the glycinate (terminating) ion; and explains why the sample and spacer gels are titrated at pH 6.7. Gly has a theoretical pI of 6.1 but, as shown by its titration curve, it is almost isoelectric, even at pH 6.7; its anionic mobility, therefore, is extremely small, in any event smaller than the slowest protein ion.

Thus, in the sample and spacer gels, two basic phenomena occur: (1) all protein ions are sorted out and physically separated according to their pI s, and (2) each protein ion is strongly concentrated in extremely thin starting zones (the disc barely a few micrometres thick and a concentration process of up to 1000- to 10 000-fold). This isotachophoretic 'train', however, does not have a long life; as it enters the running gel, the train 'runs off the tracks'. Only the 'locomotive' (Cl^-) of the train is unaffected; the various protein wagons now overrun each other, since they experience a strong frictional force, due to the highly sieving matrix, so that now their velocity is a function of their charge/size ratio. In addition, as the almost isoelectric Gly enters the pH 8.9 zone, its negative charge density strongly increases so that it jumps ahead and closely follows the Cl^- ion. As Gly sweeps down the running gel, the pH increases from pH 8.9 to 9.5 (approaching the pK value of the Gly amino group) so that now the net charge on Gly is -0.5 . As a consequence of this further jump in pH, all proteins experience an additional mobility increment. One might wonder why, after taking on such an experimental burden in forming the ITP train, one should then destroy it and continue the run in the plain zone electrophoretic mode. There are reasons for this. First, the ITP train, while maintaining high resolution due to lack of degradation of zone boundaries, has the main defect that the zones are contiguous and continuous, i.e. they are not separated by blank zones of plain buffer. As a result, when staining the gel, one would only see a single, continuous zone of protein ions, with no visible separation between zones. Second, whereas the sharp protein discs formed during the stacking (ITP) process are separated solely by surface charge, during migration in the running gel, separations continue on the basis of an additional parameter i.e. the mass. The small loss of resolution due to diffusion of the protein discs in the running gel is more than compensated for by the resolution increments due to size (coupled to charge) fractionation in this gel zone. Although disc electrophoresis is no longer in vogue, it was an extremely useful analysis technique for at least 20 years after its inception. Moreover, the general principle has not been abandoned and it is used today as a stacking technique in both SDS and capillary electrophoresis.

Disc electrophoresis could also be used for deriving physico-chemical parameters of the proteins under analysis. In 1964, Ferguson showed that one can derive parameters which are proportional to both the surface charge and the mass of the macromolecule. This can be accomplished by plotting the results of a series of experiments with polyacrylamide gels of varying porosity. For each protein under analysis, the slope of the curve $\log m_T$ (electrophoretic mobility) vs gel density (%T) is proportional to molecular mass, while the y -intercept (Y_0) is a measure of surface charge. Examples of these plots are shown in Figure 4. In Figure 4A the two parallel lines indicate charge isomers; in Figure 4B, the fanning out lines indicate a family of constant charge and different mass; in Figure 4C, the two crossing lines indicate proteins differing in both charge and mass. Recently, non-linear Ferguson plots have been reported (Chrambach, 1988), related to the reptation mode of DNA in sieving media.

Sodium Dodecyl Sulfate (SDS) Electrophoresis

SDS electrophoresis fractionates polypeptide chains essentially on the basis of their size. It is therefore a simple, yet powerful and reliable, method for molecular mass determination. In 1967 Shapiro *et al.* first reported that electrophoretic migration in SDS is proportional to the effective molecular radius and, thus, to the M_r of the polypeptide chain. This means that SDS must bind to proteins and cancel out differences in molecular charge, so that all components will migrate solely according to size. Surprisingly, large amounts of SDS appear to be bound (an average of 1.4 g SDS/g protein). This means that the number of SDS molecules bound is of the order of half the number of amino acid residues in a polypeptide chain. This amount of highly charged surfactant molecules is sufficient to overwhelm effectively the intrinsic charges of the polymer coil, so that their net charge per unit mass becomes approximately constant. If migration in SDS (and disulfide-reducing agents, such as 2-mercaptoethanol, in the denaturing step, for a proper unfolding of the proteins) is proportional only to M_r , then, in addition to cancelling out charge differences, SDS also equalizes molecular shape differences (e.g. globular vs rod-shaped molecules). This seems to be the case for protein-SDS mixed micelles. These complexes can be assumed to behave as ellipsoids of constant minor axis (*c.* 1.8 nm) and a major axis proportional to the length of the amino acid chain (i.e. to molecular mass) of the protein. The rod length for the 1.4 g SDS/g protein

Figure 4 Ferguson plots ($\log R_m$, relative mobility, vs %T, total monomer concentration) in the case of: (A) lactic dehydrogenase (LDH) 1 and 2 (isomers of charge, exhibiting the same mass); (B) serum albumin (polymeric forms, from monomer to heptamer, having constant charge and pure size difference, since all curves meet in gel-free environment, at 2% T where polyacrylamide will liquefy); (C) ferritin and ovalbumin, two totally unrelated proteins differing in both size and charge. (Parts (A) and (C) reproduced with permission from Hedrick and Smith, 1968 and Part (B) from Thorun, 1971.)

complex is of the order of 0.074 nm per amino acid residue. For further information on detergent properties, see Helenius and Simons (1975).

In SDS electrophoresis, the proteins can be prelabelled with dyes that covalently bind to their $-\text{NH}_2$ residues. The dyes can be conventional, like the blue dye Remazol, or fluorescent, such as dansyl chloride, fluorescamine, O-phthalaldehyde, and MDPF (2-methoxy-2,4-diphenyl-3[2H]-furanone). Prelabelling is compatible with SDS electrophoresis, as the size increase is minimal, but would be anathema in disc electrophoresis or IEF, as it would generate a series of bands of slightly altered mobility or pI from an otherwise homogeneous protein. Although at its inception SDS electrophoresis used continuous buffers, today the preferred set up is via discontinuous buffers and matrices, simplified from the original disc electrophoresis assembly (see Figure 5). This ensures much higher resolving power, due to formation of ultrathin protein zones.

For treatment of data, the sample and M_r standards are electrophoresed side-by-side in a gel slab. After detection of the polypeptide zones, the migration distance (or R_F) is plotted against $\log M_r$ to produce a calibration curve (Neff *et al.*, 1981) from which the M_r of the sample can be calculated (see Figure 6). It should be noted that in a gel of constant %T, linearity is obtained only in a certain range of molecular sizes. Outside this limit a new gel matrix of appropriate porosity should be used. Two classes of proteins show anomalous behaviour in SDS electrophoresis: glycoproteins (because their hydrophilic oligosaccharide units prevent hydrophobic binding of SDS micelles) and strongly basic proteins, e.g. histones (because of electrostatic binding of SDS micelles through their sulfate groups). The first anomaly can be partially alleviated by using alkaline Tris/borate buffers, which will increase the net negative charge on the glycoprotein and thus produce migration rates well correlated with molecular size. The migration of histones can be improved by using pore-gradient gels and allowing the polypeptide chains to approach the pore limit.

Porosity Gradient Gels

When macromolecules are electrophoresed in a continuously varying matrix concentration (which results in a porosity gradient) rather than in a gel of uniform concentration, the protein zones are compacted along their track, as the band front is, at any given time, at a gel concentration somewhat higher than that of the rear of the band, so that the former is decelerated continuously. A progressive band sharpening thus results. There are other reasons for resorting to gels of graded porosity. We have seen that disc electrophoresis separates macromolecules on the basis of both size and charge differences. If the influence of molecu-

Figure 5 Typical set up of a gel slab for SDS electrophoresis in a continuous (A) or discontinuous (B) gel and buffer system. In both cases, the sample is applied as a dense liquid layer in pockets precast in the gel slab by the teeth of the comb. Note that this mode of sample deposition avoids the use of the third gel phase, the sample gel, as typically adopted in disc electrophoresis.

lar charge could be eliminated, then clearly the method could be used with a suitable calibration for measuring molecular size. This has been

Figure 6 Typical $\log M_r$ vs R_F plot after an SDS-PAGE run. Note that the plot is linear only in the M_r 15 000–60 000 Da range. The M_r markers are: (1) myosin (194 000 Da); (2) RNA polymerase (β - β -subunit, 160 000 Da); (3) β -galactosidase (116 000 Da); (4) phosphorylase B (94 000 Da); (5) RNA polymerase (δ -subunit; 95 000 Da); (6) bovine serum albumin (68 000 Da); (7) ovalbumin (43 000 Da); (8) RNA polymerase (α -subunit; 38 400 Da); (9) carbonic anhydrase (30 000 Da); (10) trypsinogen (24 500 Da); (11) β -lactoglobulin (17 500 Da); and (12) lysozyme (14 500 Da). (Reproduced with permission from Neff *et al.*, 1981.)

accomplished by overcoming charge effects in two main ways. In one such way, a relatively large amount of charged ligand, such as SDS, is bound to the protein, effectively swamping the initial charges present on the protein molecules and giving a quasi-constant charge-to-mass ratio. However, in SDS electrophoresis, proteins are generally dissociated into their constituent polypeptide subunits, and the concomitant loss of functional integrity and antigenic properties cannot be prevented. Therefore, the size of the original, native molecule must be evaluated in the absence of denaturing substances.

In the second method for M_r measurement, this can be done by relying on a mathematical cancelling of charge effects, following measurement of the mobility of native proteins in gels of different concentrations. This is the so-called 'Ferguson plot' discussed above. As a third method for molecular size measurements one can use gels of graded porosity. This method is characterized by high resolving power and relative insensitivity to variability in experimental conditions. See Figure 7 for a typical experimental set up for casting porosity gradients in gel slabs. Under appropriate conditions (at least 10 kV \times hours), the mobility of most proteins becomes constant and eventually ceases as each constituent reaches a gel density region in which the average pore size approaches the diameter of the protein (pore limit) (Margolis and Kenrick, 1968). Thus, the ratio between the migration distance of a protein to that of any other becomes a constant after the proteins have all entered a gel region in which they are subjected to drastic sieving conditions. This causes the electrophoretic pattern to become constant after prolonged migration in a gel gradient. The gel concentration at which the migra-

tion rate for a given protein becomes constant is called the 'pore limit'. If this porosity is properly mapped with the aid of a suitable set of marker

proteins, it is possible to correlate the migration distance to the molecular mass of any constituent in the mixture.

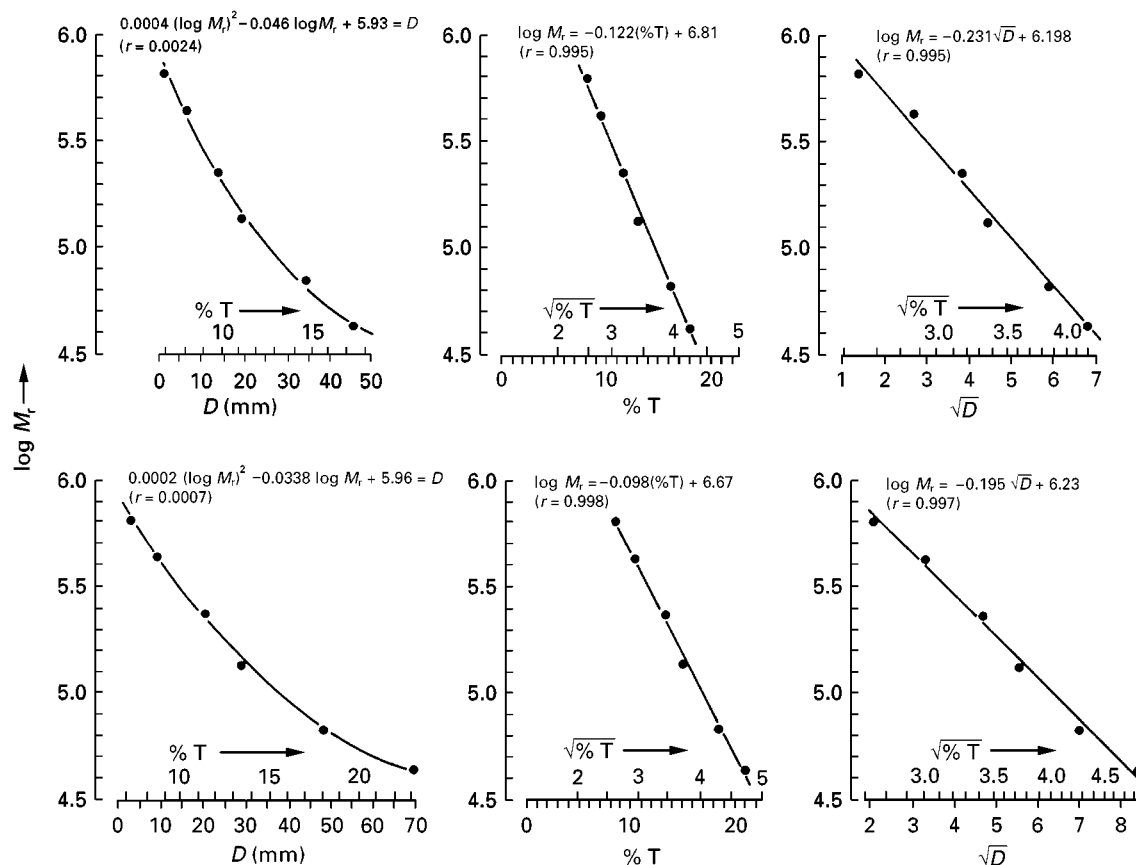

Figure 8 Typical $\log M_r$ vs migration distance (D) or gel composition (%T) plots after pore-gradient electrophoresis. Note that these plots are non-linear, whereas when $\log M_r$ is plotted against \sqrt{D} or $\sqrt{\%T}$ a linear relationship is obtained. (Reproduced with permission from Rothe and Purkhanbaba, 1982.)

After electrophoresis has finished, the experimental data gathered can be handled in two ways: a two-step or a one-step method. The most promising two-step approach appears to be that of Lambin and Fine (1979), who observed that there is a linear relationship between the migration distance of proteins and the square root of electrophoresis time, provided that time is kept between 1 and 8 h. The slopes of the regression lines of each protein in the above graph are an indication of molecular size. When the slopes of the various regression lines thus obtained are plotted against the respective molecular masses, a good linear fit is obtained, which allows M_r measurements of proteins of between 2×10^5 and 10^6 Da. The shape of the proteins (globular or fibrillar), their carbohydrate content (up to 45%) and their free electrophoretic mobilities (between 2.1 and $5.9 \times 10^{-5} \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$) do not seem to be critical for proper M_r measurements by this procedure. One-step methods have been described by Rothe and Purkhanbaba (1982). These authors found that when $\log M_r$ is plotted against either D (distance migrated) or %T (acrylamide + Bis), a nonlinear correlation is always obtained. However, when $\log M_r$ is plotted vs $\sqrt{\%T}$ or \sqrt{D} , a linear regression line is obtained, which allows the accurate determination of M_r values of proteins (standard deviation of $\pm 3.7\%$; see Figure 8. The correlations $\log M_r - \sqrt{\%T}$ or $\log M_r - \sqrt{D}$ are not significantly altered by the duration of electrophoresis. Therefore, a constant M_r value should be obtained for a stable protein, no matter how long electrophoresis takes. More recently, Rothe and Maurer (1986) have demonstrated that the relationship $\log M_r$ vs \sqrt{D} is also applicable to SDS electrophoresis in linear polyacrylamide gel gradients.

Introduction

Technical and Developmental Details of Basic Technique

Any ion will undergo electrophoresis to migrate in an electric field. Proteins are complex polyions with a net charge at all pH values other than its isoelectric point. Problems associated with convective disturbance in free solution led early researchers to consider various supporting media for electrophoresis such as paper, cellulose acetate and various thin layer materials where the separation depends largely on the charge density at a given pH. The reader should refer to the separate articles on Electrophoresis Theory and Cellulose Acetate Electrophoresis for further details. Other early workers considered the properties of various gels where the pore size approximates the size of the protein molecules themselves leading to a separation based on both charge and molecular size. The extent of molecular sieving depends on the pore size of the gel being used. For example, the pore size of agarose gels is sufficiently large that sieving of most proteins is minimal, whereas larger DNA molecules are sieved very well. Again, for a discussion of this refer to the separate article on Agarose Electrophoresis.

The pore size of polyacrylamide gels may be changed in a systematic and reproducible fashion by varying the percentage of monomer and crosslinker to give a matrix which maximizes the molecular sieving effect for a wide range of proteins and the reader should refer to the separate article on Polyacrylamide Gel Electrophoresis (PAGE) for a discussion on varying porosity in this medium.

Native proteins, however, often occur as multiple supramolecular assemblies of many peptide subunits in different configurations affected by non-covalent bonding, particularly in the case of membrane proteins. Shapiro *et al.* (1967) first demonstrated the potential of the superior protein dissociating qualities of sodium dodecyl sulfate (SDS) in an electrophoretic system designed to separate individual polypeptides on the basis of their molecular weight alone but the definitive publication in this area is undoubtedly that of Laemmli (1970) who first

combined a discontinuous buffer system (see separate article on Discontinuous Electrophoresis) with the use of SDS in sample preparation and gel electrophoresis. Protein complexes are solubilized and dissociated with such high efficiency in 2% SDS and 5% mercaptoethanol that typically over 90% of the protein in a crude lysate will enter the gel matrix and be resolved.

In the discontinuous system, proteins are dissolved by denaturing treatment at 100°C with the dissociating agents SDS and mercaptoethanol in a Tris-HCl buffer at pH 6.8. Gels are constructed in two stages both containing 0.1% SDS. The separating gel in the original Laemmli publication was formed using 30% stock acrylamide monomer with 0.8% bisacrylamide as a cross-linker. A final solution was made to 8 or 10% acrylamide containing 0.375 M Tris-HCl pH 8.8. The resolving (separating) gel is polymerized using tetramethylethylenediamine (TEMED) (catalyst) and ammonium persulfate (free radical initiator). A 'stacking' gel (at 3% acrylamide) is then cast on top of the resolving gel in the same manner but containing 0.125 M Tris-HCl at the same pH as the buffer in which the protein mixtures were dissociated (pH 6.8). The electrode buffer contains 0.025 M Tris/0.192 M glycine to a pH of 8.3 also with 0.1% SDS. Upon electrophoresis, protein anions in the form of rod-shaped SDS complexes are compressed in the stacking gel between the leading chloride ions and the trailing glycinate ions which, because of the pH difference between buffer systems, progressively close the gap as electrophoresis proceeds. (Again, see the separate articles on Discontinuous Electrophoresis and Iso-tachophoresis). The result is a concentration or stacking of the SDS-protein anions as extremely sharp bands ($\approx 5\text{--}10\text{ }\mu\text{m}$) behind the leading chloride ion in strict order of mobility. These complexes then enter the separating gel and since, supposedly, the charge-mass ratio is invariant (see later for a caveat) are separated by molecular sieving according to their molecular size only. Gels of particular acrylamide concentration and therefore pore size may be calibrated using standard proteins of known molecular weight. By extrapolation, reliable molecular weight estimates of large numbers of polypeptides in a complex mixture may be obtained. Proteins are fixed in the gel after electrophoresis using a 50% trichloroacetic acid solution and stained in a Coomassie blue solution. Radiolabelled proteins were also detected by autoradiography. For a more detailed

discussion please refer to the separate article on Detection Techniques, Staining, Autoradiography and Blotting.

In the original Laemmli procedure, gels were electrophoresed in small glass cylinders and since the absolute mobility of SDS-polypeptides varied slightly from gel to gel the relative mobility of standard and unknown bands was calculated as the ratio between the mobility of the protein and the mobility of the tracking dye, bromphenol blue (BPB), which travels with the SDS-micelle front behind the leading buffer front.

A major improvement on the original procedure uses rectangular slab gels of uniform thickness (typi-

cally 0.5–1.5 mm) with sample wells (typically 10–30) set into the stacking gel. Electrophoretic apparatus was originally constructed according to a variety of *ad hoc* patterns, in house, from perspex, using gels polymerized between notched glass plates, although now most laboratories use commercially available equipment. The use of such equipment (see the separate article on Slab Gel Electrophoresis: Equipment) has led to highly standardized reliable separations since standards and unknowns may be run under identical conditions. The apparent molecular weights of unknowns may be obtained by extrapolation from a plot of log MWt vs. mobility of standard proteins. **Figure 1** shows how individual

Figure 1 (See Colour Plate 41). The inset shows the separation of human head hair proteins using 12% sodium dodecyl sulfate-polyacrylamide gel electrophoresis with the point of migration of standard proteins to the left under the heading kDa: lanes 1–3 *S*-carboxymethylated proteins; lane 4 reduced non-*S*-carboxymethylated proteins: lane 1 ^{14}C Autoradiograph; lanes 2 and 4, silver stain; lane 3, Coomassie stain. The main body of Figure 1 shows a densitometric profile of the separated lane 1 (autoradiograph ^{14}C -*S*-carboxymethylated, green). Lane 2 (silver stain, *S*-carboxymethylated, red); lane 4 (silver stain, non-*S*-carboxymethylated). Molecular weights were extrapolated from a plot of log MWt vs. relative migration of standard proteins.

zones in a complex mixture of human hair keratins may all be assigned an apparent molecular weight and how the entire molecular weight profile is apparently shifted 20–40 kDa higher after S-carboxymethylation.

Although several alternative sample extraction and buffer systems are available (see later), the use of the basic Laemmli system has proved so robust and reliable that it has revolutionized protein characterization in complex mixtures to the extent that proteins of widely differing function are routinely described according to their apparent molecular mass on Laemmli SDS-PAGE. The explosive increase in the use of this technique across a comprehensive range of the biological sciences is illustrated in Figure 2 showing the number of citations each year of the Laemmli (1970) publication.

I will now discuss subsequent major methodological developments of the basic Laemmli protocol.

Other SDS-PAGE Systems

The SDS-PAGE technique may also be performed with the simpler continuous phosphate buffer system of Weber and Osbourne, although dilute samples are not concentrated by stacking as they are in the discontinuous system of Laemmli. In general, however, very dilute protein samples may be concentrated by precipitation with trichloroacetic acid or acetone prior to loading.

Separations of peptides and protein mixtures ranging in molecular weight from 300 kDa down to about 10–12 kDa may be optimally achieved using resolving gels of different fixed acrylamide concentrations as, for instance, shown in Figure 3A (7.5%) or B (10%) for the separation of phosphoproteins during the invasion of human red blood cells by the malarial parasite. Alternatively, a gradient mixer may be used to produce resolving gels with a linear or concave concentration gradient.

Peptides of less than 10 kDa are not resolved using the normal Laemmli system even at maximal acrylamide concentration so a variety of modified buffer systems have been introduced to allow the separation of, for example, cyanogen bromide and proteolytically cleaved peptides for structural analysis of proteins. The original Swank and Monckres system uses SDS/urea and is capable of resolution down to 2 kDa, although some undesirable modifications of amino acids may take place in the presence of urea. Other buffer systems designed to fractionate low molecular weight peptides such as the tricine and the modified Laemmli system have been more recently introduced to address this problem. For a detailed technical discussion of the preparation of gels using these various

Figure 2 The number of SCI citation of the original Laemmli, U.K. (1970) paper on sodium dodecyl sulfate-polyacrylamide gel electrophoresis for each year from 1974 (when SCI started).

buffer systems one should refer to one or more of the following generally excellent technical guides available (*Current Protocols in Molecular Biology*; *Gel Electrophoresis of Proteins – A Practical Approach*; *Protein Purification, Principles – High Resolution Methods and Techniques*).

Identification of Resolved Protein Zones

Protein bands may be directly visualized by scanning unstained unfixed gels at A_{280} but most workers employ a protein stain after fixation. Coomassie R-250 dye binds noncovalently to proteins giving deep blue bands on a clear background after diffusion (see Figure 5) or electrophoretic destaining. Alternatively, fixed proteins may be revealed by the precipitation of silver granules from an alkaline silver nitrate solution. The procedure is more complicated than the dye-binding protocol but can be up to 100 times more

Figure 3 Sodium dodecyl sulfate-polyacrylamide gel electrophoresis showing protein phosphorylation in human blood cells parasitized with the malarial organism *Plasmodium falciparum* using continuous metabolic labelling with ^{32}P phosphate. A, 7.5% Resolving gel; B, 10% Resolving gel. Mobility of molecular weight standards indicated in kiloDaltons to the right of gel A and gel B. Lane 4, infected red cell ghost 50 h post label.

sensitive. Several commercial kits are now available, ensuring the robust reproducibility of the once notoriously fickle silver staining technique. Because of this and the added sensitivity the silver staining technique has now become standard in most laboratories. Proteins vary markedly in their affinity for either Coomassie dye or silver. The insert to **Figure 1** (lanes 2 and 3) shows a comparison of the proteins separated from human hair after solubilization and carboxymethylation using either silver stain or Coomassie stain respectively. The differing sensitivities are obvious. Lane 1 shows the same proteins labelled with ^{14}C iodoacetic acid and revealed by autoradiography. Note that the lower molecular weight zones are very strongly labelled whereas they stain relatively weakly with silver (lane 2) and very poorly with Coomassie dye (lane 3).

Detection of Radiolabelled Proteins

Proteins may be radiolabelled during synthesis in the presence of labelled amino acids. ^{35}S methionine is commonly used in this regard. **Figure 4**, for instance, shows biosynthetic labelling in human lymphocytes

before and after heat shock. ^3H and ^{14}C labelled amino acids are also used as is ^{32}P phosphate (see **Figure 3**) to label phosphoamino acids. ^{35}S , ^{14}C and ^{32}P may be detected by direct autoradiography by placing fixed dried gel slabs against suitably sensitized X-ray film. The sensitivity of detection depends, on the level of incorporation of the particular

Figure 4 A 10% sodium dodecyl sulfate-polyacrylamide gel electrophoresis separation of ^{35}S methionine-labelled proteins from human lymphocytes after different recovery periods from 1 h heat shock at 42°C . Control cells from the same individual were maintained at 37°C . Lane 1, 2 h control; lane 2, 2 h after heat shock; lane 3, 3-h control; lane 4, 3 h after heat shock; lane 5, 4-h control; lane 6, 4 h after heat shock. Numbers to the right of the gel indicate the position of major heat shock proteins (hsp) induced after heat shock. Hsps are routinely classified according to their apparent molecular weight (105, 90, 70 kDa, etc.) after one-dimensional SDS-PAGE. (Thanks to my PhD student D. Visala Rao for this gel.)

amino acid into the particular protein zone but also on the isotope itself. For example after a 24-h exposure about 300–500 d.p.m.cm² of ³²P will give a visible band whereas about tenfold this level of radioactivity is required to produce a visible band using ³⁵S or ¹⁴C label. ³H label is not detected because the low β -emissions do not penetrate the gel matrix. A fluor may be introduced into the gel matrix prior to gel drying to detect ³H-labelled proteins as well as to improve the sensitivity to ¹⁴C and ³⁵S.

Proteins may also be labelled post synthetically using such reagents as ¹⁴C iodoacetic acid which preferentially labels available sulphydryl groups (see Figure 1, insert lane 1) and ¹²⁵I which preferentially labels available tyrosine groups. Many laboratories use phosphoimaging whereby the radioactive proteins in the gel excite a phosphorescent screen and the number of excitation events is directly digitized. Although this instrumentation is rather expensive it obviates the need for X-ray film and gives results in hours rather than days. Effective concentrations are said to be linear over six orders of magnitude whereas the linear range for X-ray film detection rarely covers one order of magnitude. For further details see the separate article on Detection Techniques: Staining, Autoradiography and Blotting. Radioactivity may also be quantified in gels after slicing and solubilization. In this case, a generally useful labile crosslinker N,N'-diallyltartardiamide (DATD) is often used in place of bisacrylamide.

Identity of Individual Protein Zones

The appearance of single discrete zones on SDS-PAGE, sometimes used as an indicator of homogeneity in protein purification (see Figure 5), does not preclude the possibility of multiple comigrating protein species with differing independent functions. Zones may be identified immunologically after Western blotting onto a suitable matrix and again the reader should refer to the separate article on Detection Techniques: Staining, Autoradiography and Blotting in this series for further details.

Although the process of the SDS-PAGE results in largely inactive proteins, some techniques allow *in situ* renaturation followed by specific enzyme detection (for proteases, for example). A potentially powerful development involves a second dimension SDS-PAGE separation of the entire repertoire of protein zones separated in the first dimension after co-stacking with a protease that retains its activity in the presence of SDS. In this way, a comprehensive peptide map of the proteins may be obtained and homologous proteins identified within or between species. Proteolytic fragments, so separated, may also

Figure 5 Sodium dodecyl sulfate-polyacrylamide gel electrophoresis of purified human carbonic anhydrase I. be transferred onto a PVDF membrane and sequenced.

Glycoproteins may be distinguished using the specific periodic acid-Schiffs (PAS) stain whereas phosphoproteins may be detected by intact cell metabolic labelling with ³²P phosphate (see Figure 3) or with [γ -³²P] ATP in crude lysates.

Scanning and Quantification of Individual Protein Zones

Proteins identified by specific or nonspecific staining techniques or by autoradiography or fluorography may be quantified in a relative sense after densitometric scanning of stained gels, photographs or autoradiographs. The inset to Figure 1 shows the separation of human hair proteins before (lane 4) and after (lanes 1–3) ¹⁴C-S-carboxymethylation. Proteins are detected by ¹⁴C autoradiography (lane 1),

Coomassie (lane 2) or silver stain (lanes 2 and 4). The main body of Figure 1 shows a gel scan of lane 2 (red) and lane 4 (blue) as well as the scan of the autoradiograph (lane 1, green) according to the apparent molecular weight of each component in the complex densitometric scan. Readers should refer to the separate article on Instrumentation for Scanning gels for further details in this field.

Anomalous Migration in SDS-PAGE

The precise structural relationship of SDS to protein during SDS-PAGE is unknown but various studies have indicated that a wide variety of proteins all bind a relatively constant amount of SDS ($\approx 1.4 \text{ g SDS g}^{-1}$ protein) and adopt a similar flexible rod shape regardless of their native configuration. It is this supposedly constant very high and uniform charge-mass ratio which allows for reliable molecular weight determination since migration rate therefore depends on molecular sieving alone. Having said this, even the original paper of Laemmli referred to the anomalously slow migration of a bacteriophage point mutant. The very basic proteins, histones, behave so anomalously that special buffer conditions in the presence of urea must be employed to determine reliably their molecular weights. Glycoproteins also show anomalous migration. In this laboratory we have, over the years, seen direct evidence of discrete changes in apparent migration in SDS-PAGE related to single mutations which change the charge on a protein without significantly affecting its calculated molecular weight. Figure 5, for instance, shows an SDS-PAGE separation of purified carbonic anhydrase 1 (CA1) from a Caucasian blood donor (lane 1) or an Australian Aboriginal donor (lane 4) who is heterozygous for a polymorphic variant CA1-9. The normal and the variant component of the heterozygote were resolved by isoelectric focusing (lanes 2 and 3, respectively). The variant component differed from the normal component at only one position (Asp \rightarrow Gly) although the apparent molecular weight after SDS-PAGE was 27 kDa compared with 28.5 Da. From this and other previous studies with defined point mutations of defined proteins we propose that each extra negative charge on a modified protein results in retardation on SDS-PAGE such that its apparent molecular weight is greater by 1.5 kDa. We have applied this rule of thumb to changes in the apparent molecular weights of the keratins of human hair after *S*-carboxymethylation which substitutes an extra negative charge for each thiol. See Figure 1 for general molecular weight shift of hair proteins after *S*-carboxymethylation – compare the profile from lane 4 (red) with the profile from lane 2 (blue). Given the

published molecular weights of the unmodified keratins we were then able to calculate an apparent thiol content in rough agreement with previous estimations assuming that each thiol group was substituted with an extra negative charge after carboxymethylation (lane 2).

We are therefore convinced that electrophoretic migration of SDS-protein complexes is not totally independent of charge of the native protein and furthermore that if a one-dimensional SDS-PAGE system could be suitably calibrated, the relationship we have described could become useful in studies where the net charge on a given protein is changed genetically or epigenetically in an incremental way.

Conclusions

Over the past 30 years, one-dimensional SDS-PAGE has become a standard technique in most biological and biomedical laboratories. It offers a powerful combination of resolution (up to 200–300 components in crude mixtures), reliability, versatility (pore size, extraction conditions and buffer systems can be tailored precisely to the conditions required for particular proteins) and reproducibility (different laboratories all refer confidently to certain proteins by their apparent molecular weight on SDS-PAGE, e.g. Hsp 70; see Figure 4). In addition, selectivity may be enhanced by using a variety of detection methods ranging from nonspecific staining, metabolic and postmetabolic radiolabelling to highly specific immunological detection after Western blotting. One may confidently expect that one-dimensional SDS-PAGE will continue to play a central role in protein separation in biological laboratories for many years to come, even though Figure 2 suggests that the technology uptake is now stable in that the citation rate peaked in 1990. It may be that improvements in two-dimensional technology (see the article on Two-dimensional SDS-PAGE) and the developing discipline of proteomics involving ever more powerful software to analyse complex two-dimensional protein gels will see a slow erosion of the central position of one-dimensional SDS-PAGE in isolation as method of choice in the resolution of complex protein mixtures.

Porosity Gradient Gels

G. M. Rothe, Johannes Gutenberg-University, Mainz, Germany

Copyright © 2000 Academic Press

Introduction

The high resolving power of polyacrylamide (PA) gels for proteins, peptides and nucleic acids can be improved by using gradient gels instead of homogeneous (i.e. single concentration) gels. However, a more specific separation of polynucleotides in PA gels affords separation by incorporating a 40–80% denaturant gradient (7 mol L⁻¹ urea, 40% (v/v) formamide) into a homogeneous PA gel (of e.g. 6.5% (w/v) total polymer concentration) or applying a temperature gradient to a homogeneous PA gel.

In PA gradient gels the average pore radius decreases with increasing gel concentrations, i.e. in the direction of the migrating protein (polynucleotide) bands. This results in a sharpening of the bands because the molecules at the front of the moving band are slower than those at the rear. Because of this effect, gradient gels need not be covered by a stacking gel, as in disc gel electrophoresis. In porosity gradient

gels with a steep increase of polymer concentration (e.g. from 4 to 30% T (w/v) where %T = g acrylamide + g Bis = N,N'-methylenebisacrylamide (Bis) per 100 mL) proteins of a large size range (approximately 10⁴–10⁶ Da) can be separated. In shallow gradients (> 4% T to < 30% T), the separable size range of proteins is limited but they still provide an improved band sharpening.

There are two modes to run porosity gradient gels: a fixed-time mode, where electrophoresis is terminated after a certain time, and a time-dependent mode, which means that a number of consecutive electrophoretic mobilities are registered. Fixed-time electrophoresis is performed if protein (polynucleotide) patterns are to be screened, such as in population genetics or when determining the molecular mass of sodium dodecyl sulfate (SDS) denatured proteins. Molecular size properties of non-denatured proteins, however, cannot be elucidated that way, but afford time-dependent investigation of protein mobilities. On the other hand, time-dependent PA gradient gel electrophoresis not only offers the possibility to estimate the molecular mass of native proteins and enzymes but also allows determination of their Stokes radius, frictional coefficient, free electrophoretic

mobility and nett charge. A number of different (iso)enzyme systems have been classified in this way and comparisons between related species used to study the evolution of enzyme systems.

Porosity gradient gels can be easily prepared using one of the different devices on the market. Ready-to-use pore gradient gels are commercially available (Amersham Pharmacia Biotech, Freiburg, Germany; Gradipore, 200 Harris Street, Pyrmont NSW 2009, Sydney, Australia). Porosity gradient gels can be prepared in casting glass cassettes either without any further support or by adhering them to a silanized glass plate or a reactive polyester film. The latter two methods are employed when ultra-thin gels are to be used horizontally. Glass cassette cast PA gradient gels without any further support are used vertically.

Porosity of Polyacrylamide Gradient Gels

In 1962 Ornstein and Davis were the first to suggest a formula to estimate roughly the average pore diameter of homogeneous PA gels:

$$p_{av} \text{ (nm)} = 12.67 \times (\%T)^{-1/2} \quad [1]$$

where p_{av} (nm) is the average pore diameter in nanometres and % T is the total acrylamide concentration (g acrylamide + g Bis in 100 mL).

Based on the Ogston model which describes dextran gels as assembled from arbitrarily arranged gel

rods, Raymond and Nakamichi related the average pore diameter of PA gels to the total polymer concentration (T) as follows:

$$p_{av} \text{ (nm)} = K \times d \times (100 \times p)^{1/2} \times (\%T)^{-1/2} \quad [2]$$

where K is the factor resulting from the angle in which the gel rods are linked together (1.5), d (nm) is the diameter of a PA gel rod (0.5), p (g cm⁻¹) is the density of gel rod (1.2). This results in:

$$p_{av} \text{ (nm)} = 8.216 \times (\%T)^{-1/2} \quad [3]$$

The largest pore diameter in a PA gel of a certain concentration is, however, much larger than the average pore diameter (Figure 1). Moreover, the largest pore diameter deviates increasingly from the average pore diameter with decreasing gel concentration. The pores therefore are statistically distributed, but the standard deviations of the average pore radii and the distribution function (Gaussian or logarithmic distribution) are unknown.

The generally held assumption of a random meshwork of cross-linked individual PA rods could not be confirmed by electron microscope images. They revealed sponge-like structures in the submicron range. Such structures are in accordance with the mode in which gels polymerize. PA molecules first arrange as high molecular aggregates that are in the sol state and not interconnected. Thereafter, cross-linkage to a three-dimensional gel occurs: this is indicated by an abrupt start of gelation.

Figure 1 Plot of average pore radius (r_{av} (nm)) against PA gel concentration (T (%)). Triangles, average pore radii calculated as suggested by Ornstein and Davis (1962). Squares, average pore radii calculated as suggested by Raymond and Nakamichi (1962). Circles, maximum pore radii as marked by native proteins of known radius: 1, thyroglobulin; 2, ferritin; 3, catalase; 4, lactate dehydrogenase; 5, bovine serum albumin; 6, ovalbumin. Reproduced with permission from Rothe and Maurer (1986).

Analytical Separation of Native Proteins in a Glass Cassette-Cast Porosity Gradient

Gradient preparation is performed with acrylamide solutions of high and low concentrations, usually by using a two-chamber gradient mixer, although more sophisticated gradient formers have been developed. Linear PA gradients are usually prepared by the technique which was first described by Martin and Ames in 1961 for the preparation of linear sucrose gradients. Glass cassette-cast gels are mostly 82×82 (140) mm or 125×250 mm and a thickness of 3.0, 1.0, 0.8, 0.5 or 0.1 mm.

Preparation of a Batch of Unattached Gradient Gels

Polyacrylamide gradient gels cast in glass cassettes may be prepared individually or simultaneously in batches (Figure 2). The latter method saves time and, although the gradients usually deviate slightly from each other, they are well suited to determine protein patterns, e.g. isozyme patterns as in population genetics. Any form of gradient (linear, concave, convex) may be prepared but linearly increasing gradients of total polymer concentration are most commonly used.

The device shown in Figure 3 can prepare six gradient gels simultaneously. In each gel the PA concentration increases linearly from top to bottom from approximately 5 to 25% T . The gels are encased in glass cassettes of internal dimensions 172×82

$\times 1.0$ mm. Each cassette is fitted with a slot former and inserted in a gel-casting device. The linear PA gradient is prepared by using a two-chamber gradient mixer, a separate reservoir (for the catalyst solution), a proportioning pump, a 1 mL mixing chamber (and a reservoir filled with sucrose and a pump to lift the gradient into the cassettes). The device shown in Figure 3 is used as follows: The inner chamber (1) and the connecting tube (3) to the outer chamber (2) of the gradient mixer are filled with 57 mL of T_{\min} solution. Then the tube (3) to chamber (2) of the mixer is closed. Afterwards 57 mL of the T_{\max} solution is pipetted into chamber (2) of the gradient mixer. Now 22.5 μ L of N,N,N',N' -tetramethylethylenediamine (TEMED) is mixed with the T_{\min} and the T_{\max} solution, respectively. A separate reservoir (4) is filled with 35 mL of gel buffer containing 50 mg ammonium persulfate. The connection between chamber (1) and (2) of the gradient mixer is opened, after which the stirrer (5) of the gradient mixer and the stirrer (6) of the mixing chamber (7) as well as the peristaltic pump (8) are switched on. Immediately after chamber (1) is empty, the pump (8) is switched off and a sufficient amount of sucrose solution (50% (w/v)) is pumped from the corresponding reservoir (9) with the help of a separate pump (10) underneath the gel cassettes (12) to lift the whole gradient into the cassettes, which are in the gel-casting device (14).

The T_{\min} and T_{\max} solution contain acrylamide and Bis at the same ratio (acrylamide-Bis = 24 : 1). The T_{\min} solution contains 4.205 g acrylamide and

0.175 g Bis per 100 mL gel buffer while the T_{\max} solution contains 31.54 g acrylamide and 1.314 g Bis in 100 mL gel buffer. The T_{\min} and T_{\max} solutions are diluted upon gradient formation with catalyst solution by a factor of 1.255 (Figure 3) and the gel solution is pumped to about 5 mm above the slot template. This results in a final concentration range of approximately 5–25% T . (Mixing both catalysts into the T_{\min} and T_{\max} solution is also possible but carries the danger that the gel may solidify before being completely cast in the cassette). Prior to use all solutions are brought to room temperature and degassed. The ammonium persulfate solution should be prepared freshly each time. 90 mmol L⁻¹ Tris, 45 mmol L⁻¹ boric acid and 2.5 mmol L⁻¹ EDTA-Na₂, pH 8.4 is used as gel and electrode buffer. Further buffer systems are given in Table 1.

Vertical Electrophoresis

Glass cassette-cast gradient gels are mounted vertically into an electrophoretic apparatus consisting of an upper and lower electrode vessel (Figure 4). The upper buffer tank has rubber gaskets into which two or four cassettes can be inserted. The lower electrode vessel is filled with cooled buffer; the upper electrode vessel with the inserted gel cassettes is mounted into the electrophoresis apparatus and filled with electrode buffer. Then the samples (enriched with 10% sucrose) are added to the slots (with a Hamilton syringe). Afterwards the voltage is switched on (≤ 40 V cm⁻¹) for 15 min for the proteins to migrate into the gel. Finally the buffer is circulated from buffer tank to buffer tank at the same voltage. The lower buffer tank is cooled to 5°C during electrophoresis by a cooling coil.

Table 1 Buffer systems used in porosity gradient gel electrophoresis to separate native proteins

Gel buffer	Electrode buffer	%T range	Authors
0.35 mol L ⁻¹ Tris HCl, pH 8.9	0.06 mol L ⁻¹ , Tris, 0.40 mol L ⁻¹ glycine, pH 8.3	3–20	Kopperschläger <i>et al.</i> (1969)
0.09 mol L ⁻¹ Tris, 0.08 mol L ⁻¹ boric acid, 0.003 mol L ⁻¹ EDTA–Na ₂ , pH 8.3	Same as gel buffer	4–26	Anderson <i>et al.</i> (1972) Lasky (1978)
0.01 mol L ⁻¹ Tris, 0.08 mol L ⁻¹ glycine, pH 8.3	Same as gel buffer	5–30 5–15	Slater (1969)
0.04 mol L ⁻¹ Veronal–Na, 0.04 mol L ⁻¹ Tris, 0.01 mol L ⁻¹ glycine, 0.04 mol L ⁻¹ ethanolamine, 0.001 mol L ⁻¹ EDTA–Na ₂ pH 9.8	Same as gel buffer	5–30	Lambin and Fine (1979)
0.01 mol L ⁻¹ Na–phosphate, pH 7.2	Same as gel buffer	5–30	Lambin and Fine (1979)

References as given in Rothe and Maurer (1986). Reproduced with permission from Rothe and Maurer (1986).

PA gradient gel electrophoresis under nondenaturing conditions has proved to be advantageous compared to electrophoresis in homogeneous gels, e.g. in plant population genetics. Figure 5 gives an example.

Separation of Native Proteins in an Ultra-Thin Support-Bound Porosity Gradient

To prepare a thin gradient gel of the dimensions 120 × 250 × 0.5 mm fixed to a derivatized clear and flexible polyester foil (e.g. manufactured by Gel

Bond, Marine Colloids, Rockland, MN, USA or Serva, Heidelberg, Germany), the gel-forming devices shown in Figure 6 may be used. (When the cassettes are assembled the slot formers must not touch the opposite glass wall but leave a space of 0.1 mm in between). The following solutions may be used to form a gradient ranging from 3 to 30% T:

1. gel buffer: 90 mmol L⁻¹ Tris, 80 mmol L⁻¹ boric acid, 2.5 mmol L⁻¹ EDTA–Na₂, pH 8.4;
2. electrode buffer: 1 in 2 diluted gel buffer;
3. stock acrylamide solution (30% T: 28.8 g acrylamide plus 1.2 g Bis plus 50 mL gel buffer, made to 100 mL with distilled water);

Figure 4 Vertical electrophoretic apparatus in which up to four glass cassette-cast porosity gradient gels can be inserted. Upper electrode vessel with 2 rubber gaskets to hold 2 to 4 glass cassettes, each containing a porosity gradient made of PA; +, –, electrodes. Modified from an instruction leaflet published by Pharmacia, Uppsala, Sweden.

Figure 5 Electrophoresis of plant diaphorase isoenzymes in a 4–20% *T* PA gradient gel of 0.8 mm thickness (length 175 mm, height 75 mm). (A) Zymogram of diaphorase enzymes (numbers indicate genotypes of the tetrameric enzyme at locus B). (B) Schematic representation of genotypes at locus DIA-A and DIA-B. Enzyme source: leaf buds of seven different trees of European beech (*Fagus sylvatica* L.). Conditions of electrophoresis: gel and electrode buffer: 45 mmol L⁻¹ Tris, 40 mmol L⁻¹ boric acid, 1.25 mmol L⁻¹ EDTA-Na₂; pH 8.4; running time 4 h; voltage gradient 40 V cm⁻¹; temperature 5°C.

Enzyme extraction: 1.5 mL Eppendorf tubes containing 150 mg of green bud leaves, 50 mg of quartz sand and 600 µL of extraction medium were cooled from underneath with ice water. A motor-driven grinding cone adapted in the shape of the tube (rotating at 700 rpm) was used to homogenize the material. The extraction medium contained in 100 mL: 1.21 g Tris, 1.43 g Na₂HPO₄, 60 mg L-cysteine, 210 mg ascorbic acid, 14 g sucrose, 40 mg NADP, 15 g polyclar AT (PVPP) and 1 g polyethylene glycol, pH 7.5 (with H₃PO₄). The homogenate was centrifuged for 30 min at 4°C and 10 000 *g* and the clear supernatant used as crude enzyme extract. Samples of 8 µL were applied per lane. Diaphorase isozymes were visualized histochemically (60 mL 25 mmol L⁻¹ Tris-HCl, pH 8.5, containing 24 mg NADH, 1.5 mg 2,5 dichlorophenolindophenol-Na × 2H₂O (DCPIP) and 1.8 mL MTT (500 mg 100 mL⁻¹ aq. bidest. water). Anode at bottom. A, Enzymes of gene locus DIA-A; B, locus DIA-B. In (A) not all genotypes indicated in (B) are shown.

4. dense acrylamide solution (30% *T*: to 6.5 mL stock solution is added, shortly before use, 20 µL TEMED (1 in 10 with H₂O diluted solution) and 5 µL ammonium persulfate solution (40% w/v in distilled water));
5. light acrylamide solution (3% *T*: 1 vol of stock acrylamide solution is diluted with 4.5 vol distilled water and 4.5 vol of gel buffer shortly before use and 40 µL TEMED (1 in 10 with distilled water diluted solution) and 10 µL ammonium persulfate

Figure 6 Preparation of an ultra-thin PA gradient gel fixed to a polyester foil. (A) Rolling the polyester foil (reactive side up, e.g. Gel Bond) on to one of the glass plates used to build the casting glass cassette: 1, levelling table; 2, glass plate; 3, hydrophilic side of polyester foil; 4, water layer; 5, rubber roller. (B) Trough template preparation. The bars are prepared from two layers of self-adhesive tape with a scalpel. (C) Assembling the glass cassette to cast the PA gradient. (D) Casting the porosity gradient: two-chamber mixer and glass cassette. Reproduced with permission from Rothe (1991).

solution (40% w/v in distilled water) is added. The gradient is made of 6.5 mL of dense acrylamide solution and 6.5 mL of light acrylamide solution. After gradient formation, 2 mL of light acrylamide solution is overlaid; the slots must be situated in the middle of the 3% T range.

Horizontal Electrophoresis

Before electrophoresis, the gel is taken out of the cassette. A few drops of kerosene are put on the cooling plate of the opened electrophoretic apparatus (Figure 7) and the gel, firmly adhering to the polyester foil, is placed on it, carefully avoiding the inclusion of air bubbles. Both ends of the gel are connected with the buffer vessels by paper wicks or a household sponge-like material. A 15–30 min pre-electrophor-

esis is performed at 1000 V (50 V cm^{-1}). Then the slots are filled with protein solution (or electrode buffer) and the power is turned on again at a voltage of 1000 V for approximately 2 h. Afterwards the gel, fixed on the polyester foil, may be stained for proteins or (iso)enzymes (Figure 8).

Determination of the Course and Concentration of a Porosity Gradient Gel

The course and % T range of laboratory-made PA gradient gels can be controlled by densitometry if a coloured dye such as *p*-nitrophenol is added to the denser acrylamide solution prior to gradient formation. After polymerization, the increase in colour

Figure 7 Horizontal electrophoretic apparatus with cooling plate. 1, Cover lock; 2, gassing stud; 3, high voltage connection of the lid; 4, flexible tube to the cooling plate; 7, with a cooling device (not shown); 5, electrode bar (used in isoelectric focusing); 6, electrode ledge; 8, support for cooling plate. For PA gradient gel electrophoresis the electrode bars are replaced by two buffer vessels (not shown) under the cooling plate and connected to the electrode ledge. The gel is connected to the buffer reservoirs by (paper) wicks (not shown). Reproduced with permission from Rothe (1991).

intensity from top to bottom of the gel can be used to measure the course of the gradient and its precise concentration in polyacrylamide. For a 1 mm thick gel 15 mg *p*-nitrophenol may be added to 100 mL of the dense acrylamide solution. After gelation the colour intensity is quantified by densitometry at 405 nm. Whilst the course of the gradient can be seen directly on the densitogram, the %*T* range of the gradient can be calculated with the formula:

$$T(\%) = T_s \times (E_{405} - E_p) \times M_r \times (c \times d \times \epsilon)^{-1} \quad [4]$$

where T_s (%) is PA concentration of stock solution, E_{405} is absorbance of *p*-nitrophenol, E_p is absorbance of empty cassette at 405 nm, c (g L^{-1}) is concentration of *p*-nitrophenol in stock acrylamide solution ($c = 0.150$), M_r (g L^{-1}) is mol mass of *p*-nitrophenol ($M_r = 139.1$), d (mm) is thickness of gel (e.g. 0.5), E [L (mol mm)^{-1}] = molar extinction coefficient of *p*-nitrophenol at 405 nm ($\epsilon = 1728$) and T (%), as in eqn [1].

Cross-Linkers Other than Bis and Mixed Polyacrylamide Gels

PA is normally cross-linked with Bis to obtain an electrophoretic matrix. The use of *N,N'*-(1,2-dihydroxyethylene)bisacrylamide (DHEBA) instead of Bis gives gels that can be solubilized in dilute periodic

Figure 8 Electrophoresis of plant (iso)enzymes on ultra-thin PA gradient gels fixed on a polyester film. Gel dimensions: $240 \times 120 \times 0.5$ (mm); PA gradient from 4 to 28% *T*. Enzyme source: current-year (1989) needles of Norway spruce (*Picea abies* L., Karst.) sampled from a variety of clones (clone numbers indicated) of the multiple clone variety East Prussian Late Spruce (Hessische Forstliche Versuchsanstalt, Hann. Münden, Germany). Enzyme extraction: 2 g of fresh needles was homogenized in 10 mL of homogenizing medium (0.1 mol L^{-1} Na-phosphate, pH 7.5, containing 5% w/v Polyclar AT and 0.5% w/v Triton X-100). The crude extract was centrifuged for 30 min at 38 000 g and the supernatant concentrated by a factor of 4 using the ultrafiltration system Centrisart I (Sartorius, Göttingen, Germany). Samples of $10 \mu\text{L}$ were applied per lane. Conditions of electrophoresis: 1000 V for 90 min at 4°C ; gel and electrode buffer: 45 mmol L^{-1} Tris, 40 mmol L^{-1} boric acid, 1.25 mmol L^{-1} EDTA- Na_2 , pH 8.4. Enzymes were stained histochemically. Anode at top. Reproduced with permission from Rothe (1991).

acid or dilute aqueous solutions of bases to liberate proteins after the electrophoretic separation. Gradient flat gels ($140 \times 120 \times 3$ mm) with an increasing acrylamide concentration but a constant ratio of DHEBA have been used to separate protein mixtures from fruit with radio-labelled amino acids. Following electrophoresis, gel slices containing protein zones are placed in a glass scintillation counting vial fitted with a Teflon-lined plastic cap, 1 mL of 0.025 mol L^{-1} periodic acid is added and the vials are sealed. After incubation for 48 h at 50°C , 10 mL of Mix I scintillation fluid is added, and the vials cooled overnight before counting. PA gels produced with DHEBA may be used with the common alkaline buffer systems except borate buffers, which form negatively charged complexes with the *cis*-1, 2-diol structure of the cross-linker DHEBA.

To improve the retardation of PA gradient gels for low molecular mass proteins, a mixture of acrylamide, Bis and *N,N',N'*-triallylcitric triamide has been suggested.

The use of *N*-substituted acrylamido derivatives, such as *N*-acryloyltris(hydroxymethyl)aminomethane (NAT) gives PA gels with larger pores, although the pores are still smaller than those of agarose. Gels of similar pore sizes can be made from allyl-activated agarose and acrylamide or *N*-substituted acrylamido derivatives. The mixed-bed gels of agarose-acrylamide have average pore sizes which are about 30% larger than those of a regular 3.3% Bis cross-linked gel with the same %*T*.

Size Estimation of Native Proteins and Enzymes

The size of native proteins can be deduced from their migration behaviour in homogeneous or gradient gels. Both methods have the advantage that crude tissue or cell extracts can be used as the protein source, provided a specific staining method exists with which they can be located in the gel after electrophoresis. The method with homogeneous gels uses a number of gels of different PA concentration in the range of 4–35% *T* and estimates the relative electrophoretic mobility referred to Bromophenol blue (R_F value) of a set of marker proteins and the sample protein(s). From these values the gel concentration is estimated at which the electrophoretic mobility is zero (or would become zero). This is achieved by plotting the logarithm of the %*T* concentration ($\log T$) in which the mobility is measured against the respective R_F value. In the underlying linear function ($\log T = -k \times R_F + \log T_{\text{lim}}$), the value of T_{lim} represents the exclusion limit, the %*T* concentration at which protein mobility stops. The T_{lim} values cal-

culated for a number of marker proteins can be correlated to their corresponding Stokes radii (R_S) to obtain a calibration line. A linear function is obtained when R_S is plotted against the reciprocal of T_{lim} ($R_S = a \times 1/T_{\text{lim}} + b$). Into this equation the exclusion limit of a sample protein is inserted and this then allows calculation of the corresponding Stokes radius.

Polyacrylamide gradient gel electrophoresis can also be used to estimate the molecular size of non-denatured proteins, provided it is performed in a time-dependent way. The following physicochemical properties of native proteins (enzymes) are obtainable:

1. molecular mass (M_r);
2. hydrodynamic radius (Stokes radius (R_S));
3. frictional coefficient (f/f_o) (molecular eccentricity, considering the molecular shape as a rotational ellipsoid and f/f_o as the quotient of the ratio of the two half axes of the rotational ellipsoid, f = half axis of ellipsoid, f_o = half axis of circle);
4. isomeric nature of multiple protein forms (size isomers or charge isomers);
5. free electrophoretic mobility (and nett negative charge (valence Z , charge Q)) at the pH value of the electrophoresis.

The mathematical procedures used to calculate these parameters are bound by several preconditions:

1. The PA gradient increases linearly (at a constant ratio of acrylamide to Bis). The gradient range however, can be chosen freely.
2. The electrophoretic pH value and the voltage gradient are chosen in a way that marker and sample proteins migrate sufficiently.
3. The same buffer system has been used as gel and electrode buffer, if net charges are to be obtained.
4. The sizes of the marker and sample proteins fit the pore range of the PA gradient.
5. Marker and sample proteins have migrated on the same gel slab.
6. Parts of the gel slab which have been cut into two or more parts and stained differently are re-equilibrated to the original gel length before protein migrations are measured.
7. Approximately 10 (or more) time-dependent migration distances of marker and sample proteins are accurately measured.

Estimation of the Maximum Migration Distance and Recognition of Size Isomers

With increasing times of electrophoresis under non-denaturing conditions, the migration of proteins in a PA gradient gel gradually decreases (Figures 9–11).

Figure 9 Time-dependent migration patterns of marker proteins and carbonic anhydrase (EC 4.2.1.1) (iso)enzymes from mammalian erythrocytes. Lanes 1 and 6, marker proteins. Lanes 2–5; carbonic anhydrases from (2) bovine, (3) human, (4) rabbit and (5) canine. Mol mass of marker proteins: ovalbumin (45 000), bovine serum albumin (67 000), lactate dehydrogenase (140 000), catalase (232 000), ferritin (440 000) and thyroglobulin (669 000). Linear PA 4–30% T gradient (acrylamide-Bis = 24 : 1), 300 V per 73 mm of gel length, 5°C. Running times: 2, 8 and 16 h. Gel and electrode buffer: 90 mmol L⁻¹ Tris, 80 mmol L⁻¹ boric acid, 1.25 mmol L⁻¹ EDTA-Na₂-H₂O, pH 8.4. Protein staining with Coomassie brilliant blue. Enzyme preparations from Sigma, Munich, Germany. Reproduced with permission from Rothe (1991).

Migration of globular proteins comes to an end when the maximum pore size of a gel region equals their own size. The corresponding migration distance is called the maximum migration distance (D_{\max} (mm)). The maximum migration distance can be obtained from a number of time-dependent protein migrations (D (mm)) (Figures 9 and 10) which are directly measured on the gel after proteins have been visualized following electrophoretic separation (Table 2). To obtain the maximum migration distance of a certain protein, the following mathematical approximation procedure can be applied: the migration distances are double-logarithmized ($\ln(\ln D)$) and plotted versus the reciprocal of the square root of electrophoretic migration time, $1/t^{1/2}$ (t (h)). This results in a straight line (Figure 11) whereby the transformed migration values ($\ln(\ln D)$) and the transformed times of electrophoresis ($t^{-1/2}$) are interrelated by the equation:

$$\ln(\ln D) = -a \times t^{-1/2} + b \quad [5]$$

where a and b are the slope and the intercept of the corresponding straight line. The equation predicts that at very high values of t , $t^{-1/2}$ reaches zero. This means that the maximum migration of a protein (D_{\max} (mm)) can be taken from the intercept of the straight line with the ordinate in a plot of $\ln(\ln D)$ versus $t^{-1/2}$ provided protein migrations were larger than 2 mm and a sufficient number of different migration distances are registered. Letting t approximate to infinity means that eqn [5]

becomes:

$$\ln(\ln D) = \ln(\ln D_{\max}) = b \quad [6]$$

and:

$$D = D_{\max} = \exp(e^b) \quad [7]$$

A plot of $\ln(\ln D)$ versus $t^{-1/2}$ can also be used to distinguish size isomers from charge isomers. Equally sized but differently charged forms of an enzyme or protein system are recognized by the fact that the straight line of each enzyme form intersects at the same point on the $\ln(\ln D)$ axis as is for example the case with mammalian carbonic anhydrase (cf. Figure 11) and mammalian lactate dehydrogenase. On the other hand, migration of charge isomers should result in lines of equal slope. Proteins differing in charge and size, however, give straight lines with both different slopes and intercepts.

Estimation of Stokes Radius and Molecular Mass

The maximum migration distance of globular proteins is related to the maximum gel pore radius at the respective gel concentration (cf. Figure 1). Therefore, the maximum migration distances (D_{\max}) of proteins can be correlated to their Stokes radius (R_s). A linear relationship is obtained if the logarithm of the maximum migration distance ($\ln D_{\max}$) of proteins is plotted versus the logarithm of their Stokes radius ($\ln R_s$):

$$\ln D_{\max} = -m \times \ln R_s + b \quad [8]$$

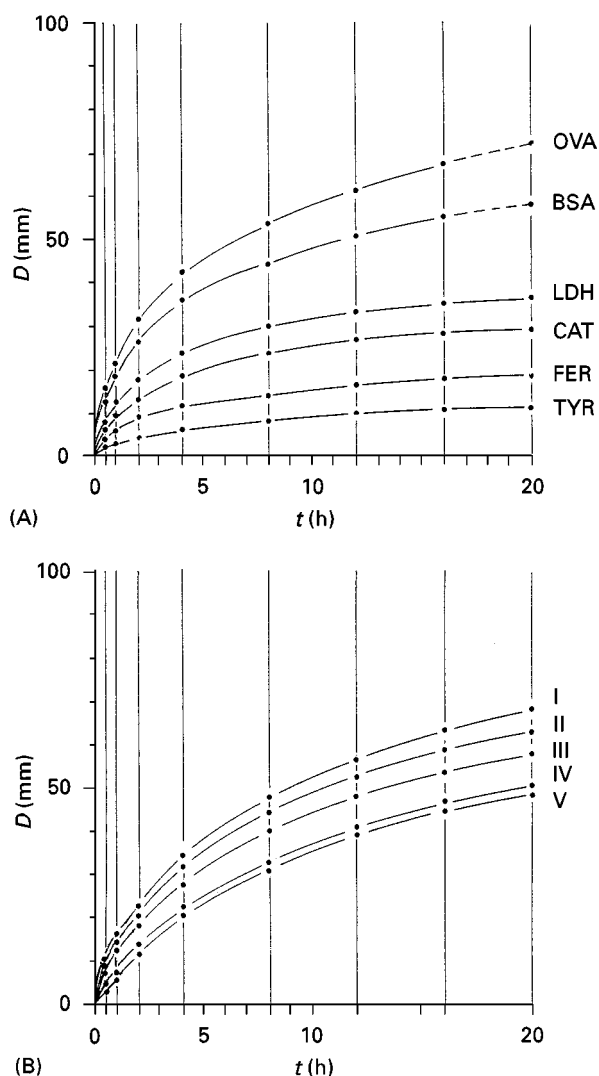

Figure 10 (A) Plot of migration distances (D (mm)) of marker proteins and (B) of five different carbonic anhydrases versus times of electrophoresis (t (h)) in a linear PA gradient gel of 4–30% T . Conditions of electrophoresis are given in Figure 9. Migration distances and times of electrophoresis as listed in Table 2. OVA, Ovalbumin; BSA, bovine serum albumin; LDH, lactate dehydrogenase; CAT, catalase; FER, ferritin; TYR, thyroglobulin. Marker proteins and carbonic anhydrases were migrated on the same gradient gel. Purified enzyme preparations (Sigma, Munich, Germany) comprised carbonic anhydrases from bovine (I–III), rabbit (III, IV), human (V) and canine (V) erythrocytes. (Reproduced with permission from Chrambach *et al. Advances in Electrophoresis* Vol 4: pp 351–358.)

where $\ln D_{\max}$ equals e^b of eqn [7], and m and b represent the slope and intercept of the straight line (Figure 12).

It has been shown that a similar equation correlates the logarithm of the maximum migration distance ($\ln D_{\max}$) to the logarithm of the molecular mass ($\ln M_r$):

$$\ln D_{\max} = -z \times \ln M_r + c \quad [9]$$

where $\ln D_{\max}$ equals e^b of eqn [7], and z and c represent the slope and intercept of the straight line (Figure 12).

Knowing the maximum migration distance of any native globular protein, the calibration line can be used to calculate the molecular mass of the protein by inserting the calculated $\ln D_{\max}$ value and the values of the slope (z) and the intercept (c) of the calibration line into the equation $\ln D_{\max} = -z \times \ln M_r + c$ (Table 3) or inserting the $\ln D_{\max}$ value and the values of the slope (m) and the intercept (b) of the calibration line into the equation $\ln D_{\max} = -m \times \ln R_s + b$ (Table 4).

When using PA gradients of 4–30% T and a buffer of pH 8.4 (45 mmol L⁻¹ Tris, 40 mmol L⁻¹ boric acid, 1.25 mmol L⁻¹ EDTA-Na₂, pH 8.4) a number of markers can be used, ranging from carbonic anhydrase (M_r 30 000, R_s 3.05) to thyroglobulin (M_r 669 000, R_s 8.50; Table 5). β -Galactosidase (M_r 116 000, R_s 4.23) and carbonic anhydrase (Sigma, St Louis, MO, USA) are run in the same lane and the other marker proteins are run in a separate one. The marker proteins bovine serum albumin, lactate dehydrogenase, catalase, ferritin and thyroglobulin can be obtained as a freeze-dried mixture (Amersham Pharmacia Biotech, Freiburg, Germany) and dissolved in a solution of pure ovalbumin (Boehringer, Mannheim, Germany). Separation times depend on the voltage gradient and may range from 0.5 to more than 20 h (Table 2).

Estimation of Frictional Coefficient

The frictional coefficient (f/f_o) relates the hydrodynamic volume of a protein molecule to its molecular mass. According to Siegel and Monty, the Stokes radius (R_s) of a protein is related to its molecular mass (M_r) by the following equation:

$$R_s \text{ (m)} = f/f_o \times (3 \times v \times M_r)^{1/3} \times (4 \times \pi \times N_A)^{-1/3} \quad [10]$$

where R_s (m) is the Stokes radius, f/f_o is the frictional coefficient (equivalent to the quotient of the half axes of a rotational ellipsoid), v (m³ g⁻¹) is the partial specific volume (the reciprocal of the average density of a protein, ($v = 0.75 \times 10^{-6}$), N_A (mol⁻¹) is Avogadro's number ($N_A = 6.022 \times 10^{23}$), and M_r (Da = g mol⁻¹) is the molecular mass of a protein. By substituting the actual values one obtains:

$$R_s \text{ (m)} = f/f_o \times 66.1 \times 10^{-12} \times M_r^{1/3} \quad [11]$$

The geometric mean radius of a molecular mass equivalent sphere is defined as R_m (m). It is obtained

Figure 11 Plot of transformed migration distances ($\ln(\ln D)$) against transformed migration times ($t^{-1/2}$) of (A) marker proteins and (B) five carbonic anhydrase variants. Migration distances and times of electrophoresis as listed in Table 2. Abbreviations as in Figure 10. The common point of intersection of the various straight lines marked I–V on the $\ln(\ln D)$ axis indicates that the investigated enzymes are size isomers. Reproduced with permission from Rothe (1991).

by setting $f/f_o = 1$ in eqn [11] to give eqn [12]:

$$R_s (\text{m}) = 66.1 \times 10^{-12} \times M_r^{1/3} \quad [12]$$

This means that R_s and R_m are interrelated through the frictional coefficient:

$$R_s = f/f_o \times R_m \quad [13]$$

The frictional coefficient can be obtained from the experimentally obtained M_r and R_s values and eqn [13].

Extremely high frictional ratios are to be expected for molecules with rod-like or fibrous structures, which are characterized by a high axial ratio such as fibrinogen or myosin or by bulky and voluminous globular molecules with normal axial ratios. Examples of the latter are the spider-like immunoglobulin M, the shell-like apoferritin or the branched α -macroglobulin. Usually, native proteins and enzymes do not belong to these groups of proteins.

In eqn [11] the frictional coefficient of native proteins is assumed to be constant. However, when analysing the molecular mass (M_r) and Stokes radius (R_s) of more than 60 native proteins it became apparent that the frictional coefficient increases with increasing protein size (see Further Reading). A more precise equation relating R_s and M_r is the following:

$$R_s (\text{m}) = M_r^{0.0225} \times 55.1 \times 10^{-12} \times M_r^{0.0142} \times M_r^{1/3} \quad [14]$$

According to this expression the frictional coefficient of globular proteins equals $f/f_o = M_r^{0.0225}$ and increases with molecular masses of 10^3 to 9×10^6 from $f/f_o = 1.17$ to $f/f_o = 1.43$ while the factor 66×10^{-12} of the expression of Siegel and Monty ($R_s (\text{nm}) = f/f_o \times 66.1 \times 10^{-12} \times M_r^{1/3}$) increases from 61×10^{-12} to 67×10^{-12} .

As an average, the frictional ratio of globular proteins sized 45–100 kDa is $f/f_o = 1.23$, for those in the range of 100–500 kDa $f/f_o = 1.28$ and in the range of

Table 2 Time-dependent migration distances of marker proteins and carbonic anhydrase (iso)enzymes from erythrocytes of four mammalian species in a porosity gradient gel from 4 to 30% *T*

D (mm), Time-dependent migration distances of marker proteins and carbonic anhydrase (EC 4.2.1.1) variants. Gel length (*D* (mm)) and gel concentration (*T* (%)) are interrelated by the equation $T = \alpha D + \beta$ where $\alpha = 0.3528 \pm 0.0054$ and $\beta = 4.1116 \pm 0.2344$; the correlation coefficient is $r = 0.9985$. Reproduced with permission from Rothe (1991).

500–1000 kDa $f/f_o = 1.43$. From these data and the Stokes radius of a globular protein its molecular mass can be estimated:

$$M_r = (1/(f/f_o))^3 \times 3463 \times R_s^3 \quad [15]$$

with M_r , f/f_o and R_s as in eqn [10].

This can be exemplified by mammalian liver alcohol dehydrogenase (EC 1.1.1.1), which has a molecular mass of 80 kDa and a Stokes radius of 3.5 nm; the

average frictional coefficient of globular proteins in that range is $f/f_o = 1.23$. By inserting these values into eqn [15] one obtains: M_r (Da) = $(1/1.23)^3 \times 3463 \times 3.5^3 = 79\,791$.

Determination of Migration Velocities

The migration velocity of a protein migrating in an electrophoretic support medium can be obtained by computing the quotient of the difference in the distance migrated between two consecutive time

Figure 12 Calibration lines to calculate the molecular mass (M) and Stokes radius (R_s) of five carbonic anhydrase isoenzymes. The logarithm of the maximum migration distance ($\ln D_{\max}$) correlates linearly to the logarithm of the mol mass ($\ln M_r$) and the logarithm of the Stokes radius ($\ln R_s$), respectively. CA, Carbonic anhydrase (average $\ln D_{\max}$ of isozymes I–V); OVA, ovalbumin; BSA, bovine serum albumin; LDH, lactate dehydrogenase; CAT, catalase; FER, ferritin; THY, thyroglobulin. The calculated mol masses and Stokes radii are listed in Tables 3 and 4.

Table 5 Marker proteins that can be used to estimate the native molecular size of proteins

Marker protein	M_r	R_s
Carbonic anhydrase	30 000	2.43
Ovalbumin	45 000	3.05
Bovine serum albumin	67 000	3.55
β -Galactosidase	116 000	4.23
Lactate dehydrogenase	140 000	4.20
Catalase	232 000	5.25
Ferritin	440 000	6.10
Thyroglobulin	669 000	8.50

M_r (Da), Molecular mass; R_s (nm), Stokes' radius of proteins. These markers can be taken when using PA gradients of 4–30% T and a buffer of pH 8.4 (45 mmol L⁻¹ Tris, 40 mmol L⁻¹ boric acid, 1.25 mmol L⁻¹ EDTA-Na₂, pH 8.4).

Correlating Migration Velocities and Migration Distances

The migration velocities may be plotted against the corresponding migration distances at the end of each time interval to correlate migration velocities and migration distances (Figure 13). The function by which v and D are interrelated is best described by the following exponential equation:

$$v \text{ (mm s}^{-1}\text{)} = \varepsilon(D_{\max} - D)^\delta \quad [17]$$

where ε , D_{\max} and δ are constants, D (mm) is the independent variable and v (mm s⁻¹) the dependent variable. D_{\max} represents the maximum migration distance which a protein can cover, i.e. the migration distance at which the migration velocity becomes zero. If this point is reached then $D_{\max} = D$ and:

$$v \text{ (mm s}^{-1}\text{)} = \varepsilon(D - D)^\delta = 0 \quad [18]$$

Eqn [17] can be used to relate the apparent migration velocity (v) of a protein to the PA concentration (T (%)) that corresponds to the migration distance travelled during a given period of electrophoresis. When using a linear gel gradient, the PA concentration and the gel length are interrelated by eqn [19]:

$$D = \alpha^{-1}(T - \beta) \quad [19]$$

whilst T_{\max} (%), the stacking gel concentration, is related to the maximum distance D_{\max} (mm) by eqn [20]:

$$D_{\max} = \alpha^{-1}(T_{\max} - \beta) \quad [20]$$

Substituting eqns [19] and [20] into eqn [17] yields the formula:

$$v \text{ (mm s}^{-1}\text{)} = \varepsilon[(T_{\max} - \beta) \times \alpha^{-1} - (T - \beta) \times \alpha^{-1}]^\delta \quad [21]$$

which can be arranged to:

$$v \text{ (mm s}^{-1}\text{)} = \varepsilon \times \alpha^{-\delta} \times (T_{\max} - T)^\delta \quad [22]$$

and:

$$v \text{ (mm s}^{-1}\text{)} = h \times (T_{\max} - T)^\delta \quad [23]$$

where $h = \varepsilon \times \alpha^{-\delta}$.

This derivation shows that, indeed, the apparent migration velocity of a protein (v) is related by the same function to the distance (D) as to the PA concentration (T) it has reached in a linear pore gradient, although the constants (ε and D_{\max} , respectively, h and T_{\max}) are different. The exponent δ in both equations, however, is the same.

Eqn [23] predicts that zero protein mobility ($v = 0$) results if the apparent gel concentration (T (%)) is equal to the stacking gel concentration (T_{\max} (%)), i.e. if $T = T_{\max}$. The apparent free electrophoretic mobility of a protein unhindered by the PA matrix (μ (mm s⁻¹)), can be calculated by simply extrapolating its apparent mobility to zero T (%):

$$\mu \text{ (mm s}^{-1}\text{)} = h \times (T_{\max} - 0)^\delta \quad [24]$$

thus:

$$\mu \text{ (mm s}^{-1}\text{)} = h \times T_{\max}^\delta \quad [25]$$

This expression may be used to divide eqn [23] to yield eqns [26] and [27]:

$$v \times \mu^{-1} = (h \times (T_{\max} - T)^\delta) \times (h \times T_{\max}^\delta)^{-1} \quad [26]$$

which can be rewritten as:

$$v = \mu[1 - (T \times T_{\max}^{-1})]^\delta \quad [27]$$

The value of the quotient $(T_{\max} - T) \times T_{\max}^{-1}$ ranges from one ($T = 0$) to zero ($T = T_{\max}$) and thus the value of v extends from the apparent free electrophoretic mobility (μ) to zero.

This means that, in a linear PA gradient, the apparent migration velocity (v) of a protein (migrating under a constant electrical field strength) is equal to its apparent free mobility (μ) times a retardation factor $[1 - (T \times T_{\max}^{-1})]^\delta$ which depends on the PA concentration (T) that the protein has just reached and its exclusion limit (T_{\max}). This factor always takes

Figure 13 (A) Estimation of the migration velocity of a protein (OVA, ovalbumin) in a linear PA gradient gel. T_n , migration distance at a longer time of electrophoresis (t_n); T_m , migration distance at a shorter time of electrophoresis (t_m). (B) Plot of the resulting migration velocities (v (mm s $^{-1}$) versus the corresponding gel concentrations (T (%)) at the end of each time interval.

values between zero and one and increases exponentially with increasing gel concentrations.

In order to solve eqn [23] (v (mm s $^{-1}$) = $h \times (T_{\max} - T)^\delta$), the following sequence of calculations is recommended:

1. determination of the maximum migration distance of the protein under investigation from a plot of $\ln(\ln D)$ vs. $t^{-1/2}$ (eqn [5])
2. computation of the maximum gel concentration (T_{\max}) by use of eqn [20] ($D_{\max} = \alpha^{-1}(T_{\max} - \beta)$);
3. calculation of the gel concentration equivalent to the migration distances with eqn [19] ($D = \alpha^{-1}(T - \beta)$), (the values of the constants α and β may be obtained from a gel scan at 405 nm if *p*-nitrophenol has been mixed into the more concentrated of the two solutions used to prepare the gradient gel);
4. then the values of $(T_{\max} - T)$ are calculated
5. finally the constants h and δ in eqn [23] are calculated by plotting $\ln v$ vs. $\ln(T_{\max} - T)$ and performing a linear regression analysis with these data,

i.e. taking the logarithmized version of eqn [23]:

$$\ln v = \delta \times \ln(T_{\max} - T) + \ln b \quad [28]$$

Calculation of the Free Electrophoretic Mobility

The free electrophoretic mobility (U ($\text{m}^2 \text{V}^{-1} \text{s}^{-1}$)) of a protein results from its apparent free electrophoretic mobility unhindered by the gel matrix (μ ($\text{m} \text{s}^{-1}$)) and the electric field strength E (V m^{-1}) acting on it:

$$U = \mu \times E^{-1} (\text{m s}^{-1} (\text{V m}^{-1})^{-1} = \text{m}^2 \text{V}^{-1} \text{s}^{-1}) \quad [29]$$

The apparent free electrophoretic mobility can be obtained by applying eqn [25] (μ (mm s^{-1}) = $b \times T_{\max}^{\delta}$). The free electrophoretic mobilities of various marker proteins and five different mammalian carbonic anhydrases calculated by these procedures are listed in Table 6.

Computation of the Nett Charge

Estimation of the number of unit charges (Z) in a nondenatured protein requires prior knowledge of its Stokes radius (R_s) and its apparent free electrophoretic mobility (μ) or its free electrophoretic mobility (U). In addition to this, the ionic strength (I) and viscosity (η) of the buffer system used to estimate Z and R_s must be known. Time-dependent gradient gel electrophoresis can be used to determine the Stokes radius of a protein and its free electrophoretic mobility.

At a first approximation, the free electrophoretic mobility, unhindered by a gel matrix (U ($\text{m}^2 \text{V}^{-1} \text{s}^{-1}$)), can be described by eqn [30]:

$$U = (Z \times \varepsilon) \times (6 \times \pi \times \eta \times R_s)^{-1} \\ (C (\text{Pa s m})^{-1} = \text{m}^2 (\text{V s}^{-1})) \quad [30]$$

where Z is the number of unit charges (1); ε is the unit charge (protonic charge) = 1.602×10^{-19} (C); $\pi = 3.14 \dots$; η is the dynamic viscosity of the medium (Pa s); R_s is the Stokes radius (m) and the following coherences $1 \text{ C} = 1 \text{ A s}$, $1 \text{ Pa} = 1 \text{ N m}^{-2}$, $1 \text{ V A} = 1 \text{ W}$ and $1 \text{ W s} = 1 \text{ N m}$.

Since migration of proteins is studied in buffered solutions, there are also positive and negative buffer ions present, in addition to the protein ions. The small ions of sign opposite to that of the protein, also called counterions, are present in excess and to be found in the vicinity of the protein molecules. The electric field which drives the protein molecules also acts on the counterions, but in the opposite direction and since the migrating counterions drag solvent along with them and the solvent in turn acts on the protein, the nett effect is a secondary force on the protein opposite in direction to the primary force. The migration velocity of the protein molecules towards the electric field may therefore be reduced well below that predicted by eqn [30], an effect known as the electrophoretic effect. This is why eqn [30] must be corrected by a retardation factor (F),

Table 6 Free electrophoretic mobility (U) and net negative charge (valence, Z ; charge, Q) of several marker proteins and carbonic anhydrase (iso)enzymes from mammalia at pH 8.4

Protein	U ($\text{m}^2 (\text{V s})^{-1} \times 10^{-9}$) $I = 0.529 \times 10^{3a}$ (mol m^{-3})	Negative charge

the quantity of which depends on the composition and strength of the small ions of the buffer used. Henry proposed a method for computing this factor using the formula:

$$F = (X_1(\kappa \times R_s)) \times (1 + (\kappa \times R_s))^{-1} \quad [31]$$

where X_1 is a function of $\kappa \times R_s$. Introducing this factor into eqn [30] yields eqn [32]:

$$U = (Z \times \varepsilon) \times (6 \times \pi \times \eta \times R_s)^{-1} \times (X_1(\kappa \times R_s)) \times (1 + (\kappa \times R_s))^{-1} \text{ (m}^2 \text{ V s}^{-1}\text{)} \quad [32]$$

The function $X_1(\kappa \times R_s)$ is complicated but always gives values between 1.0 and 1.5, as shown in **Figure 14**. According to Henry, three different equations must be used to compute the values of the function X_1 . If $\kappa \times R_s > 24$ then the first of the three equations indicated in **Figure 14** must be used. When $\kappa \times R_s \leq 5$ the last of the three equations in **Figure 14** is applied. In the range between the two border values 5 and 24, a linear equation is taken, which is also

given in **Figure 14**. It is somewhat difficult to calculate the X_1 values when $\kappa \times R_s \leq 5$. Therefore, **Table 7** provides a number of values in the range of $\kappa \times R_s = 0.01$ –5. Kappa ($\kappa \text{ (m}^{-1}\text{)}$) represents the reciprocal of the radius of the ion cloud, i.e. the radius of the cloud of counterions surrounding the protein. Depending on the ionic composition, ionic strength and temperature of the solution, κ acquires values ranging from zero to infinity, and at increasing ionic strengths the value of κ increases whilst the radius of the ionic cloud decreases and vice versa. In a salt-free solution, $\kappa = 0$ so that the electrophoretic mobility U is not influenced at all, whilst conversely it decreases permanently in solutions with increasing salt concentrations. The value of kappa can be obtained from the equation:

$$\kappa = [(2N_A \times \varepsilon^2) \times (D_0 \times D \times k \times T)^{-1}]^{1/2} \times I^{1/2} \text{ (m}^{-1}\text{)} \quad [33]$$

where $N_A = 6.025 \times 10^{23} \text{ (mol}^{-1}\text{)}$; ε is the unit charge (protonic charge) = $1.602 \times 10^{-19} \text{ (C)}$; D_0 represents

Figure 14 Graphical representation of Henry's function $X_1(\kappa R_s)$. Depending on the value of κR_s three different equations must be used to compute the values of X_1 . If $\kappa R_s > 24$ (case 1), the first of the three equations given is used. The second equation (case 2) comes into use if $5 \leq \kappa R_s \leq 24$ while the third equation (case 3) is applied if $\kappa R_s \leq 5$. In the latter case, Table 6 provides a number of values. Reproduced with permission from Rothe (1991).

^aValues were calculated using eqn [3] of Figure 14 (cf. Overbeek JTG (1950) *Advances in Colloid Science*, 3: 97-135). Tolerance of values: 10^{-6} , calculation of integral: 7 digits. Data from Rothe (1991).

the dielectric constant of vacuum = 8.8542×10^{-12} ($\text{C V}^{-1} \text{m}^{-1} = \text{C}^2 \text{N}^{-1} \text{m}^{-2}$); D is the temperature-dependent dielectric constant of water (without dimension, cf. Table 8), k is Boltzmann's con-

stant = 1.3805×10^{-23} ($\text{J K}^{-1} = \text{N m K}^{-1}$); T is absolute temperature (K) and I is the ionic strength (mol m^{-3}) of the buffer that was used for electrophoresis.

Table 8 Dielectric constant (D) of water depending on the temperature t ($^{\circ}\text{C}$)

t ($^{\circ}\text{C}$)	D	t ($^{\circ}\text{C}$)	D
0	87.90	18	80.93
5	85.90	20	80.18
10	83.95	25	78.36
15	82.04	30	76.58

Reproduced with permission from West (1976–1977).

By substituting these values into the equation one obtains:

$$\kappa = [(2 \times 6.025 \times 10^{23} \times (1.602 \times 10^{-19})^2) \times (8.8542 \times 10^{-12} \times 1.3805 \times 10^{-23})^{-1}]^{1/2} (\text{K m} (\text{mol})^{-1})^{1/2} \times (I (D T)^{-1})^{1/2} (\text{mol m}^{-3} \text{K}^{-1})^{1/2} \quad [34]$$

thus:

$$\kappa = 1.590608013 \times 10^{10} (\text{K m mol}^{-1})^{1/2} \times (I (D T)^{-1})^{1/2} (\text{mol m}^{-3} \text{K}^{-1})^{1/2} \quad [35]$$

At a temperature of 5°C (278 K), the dielectric constant of water is 85.90 (cf. Table 8). Inserting both values into eqn [35] yields eqn [36]:

$$\kappa = 1.02930525 \times 10^8 (\text{m mol}^{-1})^{1/2} \times \sqrt{I (\text{mol m}^{-3})^{1/2}} \quad [36]$$

The ionic strength I (mol m^{-3}) is calculated using the formula:

$$I = 1/2 \sum c_i Z_i^2 (\text{mol m}^{-3}) \quad [37]$$

where $\sum c_i$ (mol m^{-3}) represents the concentrations of the ionic species of the buffer times their squared charges (Z_i).

Taking, for example, a 90 mmol L^{-1} Tris, 80 mmol L^{-1} boric acid, 1.25 mmol L^{-1} EDTA- Na_2 buffer of pH 8.0, the ionic strength of this buffer is:

$$I = 1/2 \sum c_i Z_i^2 (\text{mol dm}^{-3}) \quad [38]$$

thus:

$$I = 1/2 [(0.09 \times 1^2) + (3 \times 0.08 \times 1^2) + (0.08 \times (-3)^2) + (2 \times 0.00125 \times 1^2) + (0.00125 \times (-2)^2)] \quad [39]$$

which becomes:

$$I = 0.52875 (\text{mol dm}^{-3}) \quad [40]$$

or:

$$I = 0.52875 \times 10^3 (\text{mol m}^{-3}) \quad [41]$$

Substituting this value into eqn [36] gives:

$$\kappa = 1.02930525 \times 10^8 (\text{m mol}^{-1})^{1/2} \times (528.75)^{1/2} (\text{mol m}^{-3})^{1/2} \quad [42]$$

which rearranges to:

$$\kappa = 2.366842604 \times 10^9 (\text{m}^{-1}) \quad [43]$$

Taking ferritin as an example, with a Stokes radius of 6.20×10^{-9} (m), then $\kappa \times R_s = 14.67$. The log of $\kappa \times R_s$ equals 1.167 and using this value one obtains from the equation in case 2 shown in Figure 14, a value of 1.293 for the function X_1 ($\kappa \times R_s$). Thus, inserting these values into eqn [31], it follows that:

$$F = (X_1(\kappa \times R_s)) \times (1 + (\kappa \times R_s))^{-1} = 1.293 \times (1 + 14.67)^{-1} = 0.08251 \quad [44]$$

To calculate the number of nett charges in ferritin, eqn [32] must be solved for Z :

$$Z = ((U \times 6 \times \pi \times \eta \times R_s) \times \epsilon^{-1}) \times ((1 + (\kappa \times R_s)) \times (X_1(\kappa \times R_s))^{-1}) \quad [45]$$

From gradient gel electrophoresis results, the free electrophoretic mobility of ferritin was calculated as $U = 3.28 \times 10^{-9}$ ($\text{m}^2 \text{V}^{-1} \text{s}^{-1}$). Substituting this value, that of factor F and the value for the temperature-dependent dynamic viscosity (η (N s m^{-2})) of water as taken from Table 9 into eqn [45], the number of unit charges that ferritin acquires under the electrophoretic conditions indicated above can be computed as:

$$Z = (3.28 \times 10^{-9} \times 6 \times \pi \times 1.519 \times 10^{-3} \times 6.20 \times 10^{-9}) \times (1.602 \times 10^{-19})^{-1} \times ((1 \times 0.08251)^{-1}) \quad [46]$$

which works out to:

$$Z = 44.05 \quad [47]$$

The actual charge on the molecule is given by $Z \times \epsilon$ [C molecule^{-1}] = $44.05 \times 1.602 \times 10^{-19} = 7.057 \times 10^{-18}$ (Table 6).

Table 9 Dynamic viscosity (η (N s m⁻²)) of water depending on the temperature (t (°C))

Evaluation of the Free Electrophoretic Mobility at an Ionic Strength of 0.1 mol L⁻¹

For reasons of comparability, the free electrophoretic mobility obtained for a given set of experimental conditions may be corrected to an effective mobility at an ionic strength of 0.1 mol L⁻¹. This can be achieved by substituting the relevant values into Abramson's equation:

$$U_{0.1} = (U_{>0.1}(\kappa_{>0.1} \times R_S + 2.4)) \times (\kappa_{0.1} \times R_S + 2.4)^{-1} \quad [48]$$

where $U_{0.1}$ and $U_{>0.1}$ (m² V⁻¹ s⁻¹) represent the free electrophoretic mobilities at an ionic strength of 0.1 (mol m⁻³) and > 0.1 (mol m⁻³) respectively; $\kappa_{>0.1}$ and $\kappa_{0.1}$ represent the reciprocal of the effective thickness of the ionic cloud at ionic strength of 0.1 (mol m⁻³) and > 0.1 (mol m⁻³) respectively and R_S (m) is the Stokes radius of the protein.

For the experimental conditions given earlier:

$$\kappa_{0.1} = 1.02930525 \times 10^8 \text{ (m mol}^{-1}\text{)}^{1/2} \times (0.1 \times 10^3)^{1/2} \text{ (mol m}^{-3}\text{)}^{1/2} \quad [49]$$

thus:

$$\kappa = 1.02930525 \times 10^9 \text{ (m}^{-1}\text{)} \quad [50]$$

Taking ferritin as an example, for which U (m² V⁻¹ s⁻¹) = 3.28×10^{-9} (at $I = 0.529 \times 10^3$ (mol m⁻³), if $\kappa_{>0.1} = 2.366842604 \times 10^9$ and $R_S = 6.20 \times 10^{-9}$ (m) are determined and substituted into eqn [48], it follows that:

$$U_{0.1} = ((3.28 \times 10^{-9}) \times (2.366842604 \times 10^9 \times 6.20 \times 10^{-9} + 2.4)) \times (1.02930525 \times 10^9 \times 6.20 \times 10^{-9} + 2.4)^{-1} \quad [51]$$

thus:

$$U_{0.1} = 6.377 \times 10^{-9} \text{ (m}^2 \text{ V}^{-1} \text{ s}^{-1}\text{)} \quad [52]$$

The free electrophoretic mobilities at $I = 0.52875 \times 10^3$ (mol m⁻³) and at $I = 0.1 \times 10^3$ (mol m⁻³) of several marker proteins and some carbonic anhydrase isozymes are listed in Table 10.

Table 10 Free electrophoretic mobility of ferritin in buffered solution

Experimental conditions	Free mobility U (m ² V ⁻¹ s ⁻¹) $\times 10^{-9}$	Reference
Moving boundary method $I = 0.1$ (mol L ⁻¹), 0 (°C), pH 8.6	– 6.1	Mazur <i>et al.</i> (1950)
Agarose gel electrophoresis $I = 0.05$ (mol L ⁻¹), + 20 (°C), pH 6.8	– 10.5	Gosh <i>et al.</i> (1974)
Disc electrophoresis $C = 2\%$; 0 (°C), pH 8.88 $I = 0.0034$ (mol L ⁻¹) $I = 0.10$ (mol L ⁻¹)	– 10.97 – 5.67	Rodbard <i>et al.</i> (1971)
PA gradient gel electrophoresis 5–30 T (%), acrylamide–Bis = 24 : 1; + 4 (°C), pH 8.4 ^a $I = 0.529$ (mol L ⁻¹) $I = 0.10$ (mol L ⁻¹)	– 3.28 – 6.38	Rothe (1991)

^aElectrophoretic conditions; 90 mmol L⁻¹ Tris, 80 mmol L⁻¹ boric acid, 1.25 mmol L⁻¹ EDTA–Na₂, pH 8.4; separation distance 73 mm, voltage gradient 41.1 (V cm⁻¹)

References are given in Rothe (1991).

The result of calculating the net protonic charge of a protein of course remains unaffected whether the ionic strength of the experiment or that of a buffer strength of 0.1 mol L^{-1} is used.

Comprehensive Equation Describing Electrophoretic Mobility of Proteins Migrating in a Linear PA Gradient Gel

As explained above, the velocity with which a protein migrates in a linear PA gradient gel depends on its apparent free electrophoretic mobility times a retardation factor (eqn [27]):

$$v = \mu \times [1 - (T \times T_{\max}^{-1})]^\delta \text{ (m s}^{-1}\text{)} \quad [27]$$

where v is the migration velocity (m s^{-1}), T (%) is the PA concentration which the migrating protein of mobility v has reached and T_{\max} (%) represents the exclusion limit of the migrating protein.

Since $U = \mu \times E^{-1}$ ($\text{m}^2 \text{V}^{-1} \text{s}^{-1}$), it follows that:

$$v \times E^{-1} = U \times [1 - (T \times T_{\max}^{-1})]^\delta \text{ (m V}^{-1} \text{s}^{-1}\text{)} \quad [53]$$

U is defined by eqn [32] as equivalent to:

$$U = (Z \times \varepsilon) \times (6 \times \pi \times \eta \times R_s)^{-1} \times (X_1(\kappa \times R_s)) \times (1 + (\kappa \times R_s))^{-1} \text{ (m}^2 \text{V s}^{-1}\text{)}$$

with the definitions given above.

Using all this information, a complete description of the electrophoretic mobility of proteins migrating in a linear PA gradient gel can then be given by the equation:

$$v \times E^{-1} = (Z \times \varepsilon) \times (6 \times \pi \times \eta \times R_s)^{-1} \times (X_1(\kappa \times R_s)) \times (1 + (\kappa \times R_s))^{-1} \times [1 - (T \times T_{\max}^{-1})]^\delta \text{ (m}^2 \text{V s}^{-1}\text{)} \quad [54]$$

with the definitions as given above.

Sodium Dodecyl sulfate Porosity Gradient Gel Electrophoresis

Polyacrylamide gradient gels also offer greater possibilities for the electrophoretic separation of proteins in the presence of SDS. Porosity gradient gels have a much higher resolving capacity, for example the two chains of haemoglobin of $M_r = 15\,126$ and $15\,866$ Da, respectively, can be clearly separated in a 3–30% T gradient gel. An 8% T continuous PA-SDS gel does not exhibit this resolving capacity. In SDS porosity gradient gel electrophoresis the

use of continuous buffer systems is recommended (Table 11) since partial deloading of SDS-protein complexes has been observed when the gel contained SDS but not the electrode buffer. This results in a confusing multitude of bands.

Estimation of Molecular Mass of Denatured Proteins and Small Peptides

When SDS electrophoresis is performed in a linear PA gradient gel of 3–30% T , a linear relationship can be set up between the logarithm of the mol mass ($\log M_r$) and the log of the PA concentration ($\log T$) reached by proteins after a certain time of electrophoresis. The validity of the corresponding relationship $\log M_r = -a \times \log T + b$ has been confirmed with some 40 proteins between 14 and 950 kDa. In PA gradient gels in the presence of SDS the molar mass of both unreduced and 2-mercaptoethanol-reduced proteins as well as the molar mass of glycoproteins can be determined with the same accuracy ($\pm 5\%$, Table 12). Ribonuclease and lysozyme binding normal amounts of SDS migrate anomalously in homogeneous SDS gels but not in SDS PA gradient gels. Papain and pepsin, which also bind only traces of SDS, migrate regularly in SDS PA gradient gels.

The migration distance of proteins in linear SDS PA gradient gels and their respective mol mass can also be correlated by the equation:

$$\log M_r = -a \times \sqrt{D} + b \quad [55]$$

where D (mm) is the migration distance. This relationship can be applied to SDS-complexed and reduced and to SDS-complexed nonreduced proteins, to glycoproteins and to carbohydrate-free proteins (Figure 15). The relationship is not affected by the buffer system, the concentration of the cross-linker within 1–8% C or the concentration range of the gradient within 3–30% T at the commonly used gel length of 8–15 cm. The value of the constants a and b , on the other hand, are changed when the experimental parameters are altered. If SDS electrophoresis is performed in a linear gradient gel of approximately 6–27% T , the relationship $\log M_r = -a \times \sqrt{D} + b$ is practically independent of the time of electrophoresis. This means that the molecular mass estimation can be made when the best resolution of a set of proteins has been obtained. It is not necessary to wait until the proteins have reached their exclusion pore size. On the contrary, under prolonged electrophoresis protein-SDS complexes can reach a pore size where the complexing SDS is stripped off the protein molecules which leads to erroneous banding patterns. This is particularly

Table 11 Gel and buffer systems used in SDS PA gradient gel electrophoresis to separate denatured proteins

PA range (%T) (acrylamide-Bis)	Gel shape (dimensions (mm))	Buffer systems		Current or voltage per gel	Running time (h)	Correlation (M_r range (kDa))	Notes	Authors

1.5–40 (12.57 : 1)	Microcolumn i.d. 0.43, length 15	0.1 mol L ⁻¹ Na-phosphate, pH 7.2, 0.1% SDS or 0.35 mol L ⁻¹ Tris-sulfate, 0.1% SDS, pH 8.5, or 0.05 mol L ⁻¹ Tris-glycine, 0.1% SDS, pH 8.4, or 0.065 mol L ⁻¹ Tris-borate, 0.1% SDS, pH 9.3	29 g glycine plus Tris to pH 8.4, 1 g SDS, H ₂ O to 1000 mL	60 V	2	log M_r vs. R_F (13–300)	<i>c</i>	Rüchel <i>et al.</i> (1974)
1.5–40 (12.57 : 1)	Microcolumn (i.d. 0.43, length 15)	4 g Tris and H ₂ SO ₄ to pH 8.4, H ₂ O to 10 mL	29 g glycine plus Tris to pH 8.4, 1 g SDS, H ₂ O to 1000 mL	60 V	0.33	log M_r vs. R_F (13–300)	<i>c</i>	Rüchel <i>et al.</i> (1974)
3–30 (28 : 1)	Slab gel (width 80, length 80, thickness 1)	0.04 mol L ⁻¹ Tris, 0.02 mol L ⁻¹ Na-acetate, 0.02 mol L ⁻¹ Na-EDTA, pH 7.4, 0.2% SDS	Same as gel buffer	150 V	0.5–8	log M_r vs. \sqrt{D} (13–950)	<i>d</i>	Rothe (1982)

^aGels were stored at room temperature before use in a solution which contained 0.1 mol L⁻¹ Na-phosphate, 0.01% SDS, 15% glycerol, 2 mmol L⁻¹ EDTA-Na₂ and 0.01% NaN₃. Samples were dissolved at 100°C for 3 min in 0.01 phosphate buffer, pH 7, containing 2.5% SDS, 5% 2-mercaptoethanol, 10% glycerol and 0.005% Bromophenol blue. On each column 20–100 µg protein was loaded.

^b T (%) g acrylamide plus g Bis per 100 mL solvent. Protein samples (0.5 mg mL⁻¹) were incubated in 0.01 mol L⁻¹ phosphate buffer, containing 1% SDS, pH 7.2 for 3 min in a 100°C bath; for cleavage of disulfide bridges 1% 2-mercaptoethanol was added. The % T concentration reached by each protein after electrophoresis was determined and log T plotted versus log $mol\ mass$.

^cResolution was found to be better in discontinuous than in continuous buffer systems. Samples (1 mg protein mL⁻¹) were treated for 2 min at 100°C with 1% SDS and 1% 2-mercaptoethanol in 0.035 mol L⁻¹ Tris-sulfate, pH 8.6, 0.35 mol L⁻¹ Tris-sulfate, pH 8.6 or 0.1 mol L⁻¹ phosphate. Complete removal of SDS from proteins can be achieved with SDS-free electrode buffers. The activity of β -galactosidase denatured with SDS and separated on an SDS-free PA gradient gel could be restored to 10%.

^d \sqrt{D} , square root of migration distance (D (mm)). Re-evaluation of the data from Lambin (1978), Lasky (1978) and Poduslo and Rodbard (1980) confirmed the validity of the log M_r – \sqrt{D} relationship, found when evaluating time-dependent SDS-porosity gradient gel electrophoresis using marker proteins in the range of 10–330 kDa.

true when in an alkaline buffer system the upper electrode buffer contains no SDS.

In SDS electrophoresis with linear PA gradients ranging from 3 to 30% T , polypeptides in the range

of 1.4–10 kDa cannot be resolved. Separation is possible, however, in 10–18% T gels in the presence of 0.1% SDS and 7 mol L⁻¹ urea (cf. Tables 13 and 14).

Separation of Urinary Proteins and Diagnosis of Proteinurias

Diagnosis of pathological urinary profiles and estimation of the molecular size of the corresponding

proteins is possible by SDS PA gradient gel electrophoresis under nonreducing conditions. Protein patterns may be estimated in micro-sized ($43 \times 50 \times 0.45$ mm) SDS gradient gels of 8–25% T fixed to a plastic backing (GelBondTM) as they are

Figure 15 Migration distances of denatured proteins and protein subunits obtained by SDS PA gradient gel electrophoresis. The logarithm of the molecular mass of proteins ($\log M_r$) is linearly correlated to the square root of the PA concentration ($\sqrt{\%T}$) which they reached upon electrophoresis. Also, $\log M_r$ is linearly correlated to the square root of the migration distance (\sqrt{D} (D (mm))) which proteins reached upon electrophoresis. Reproduced with permission from Rothe (1994).

commercially available together with a suitable horizontal electrophoretic apparatus (Phast system) and an automated silver staining device (Amersham Pharmacia Biotech). The method has the advantage that urine samples need not be concentrated or desalted before electrophoresis. Samples may be stored frozen at -20°C after addition of sodium azide and after particulate removal by centrifugation. Samples with

protein concentrations above 0.30 mg mL^{-1} must be diluted. Proteins must not be reduced (e.g. with 2-mercaptoethanol) since under SDS and nonreducing conditions the quaternary structure of all major serum proteins excreted in urine is unaffected, except haemoglobin which is split into its monomers and dimers. **Figure 16** shows some selected protein patterns of renal malfunctions.

Table 13 Gel and buffer system used to separate small peptides in SDS PA gradient gel electrophoresis

Acrylamide (g 100 mL ⁻¹)	Bis (g 100 mL ⁻¹)	Gel buffer (pH)	Electrode buffer (pH)	Correlation (M_r (Da) range)	Authors
10–18	0.5–0.9	Stacking gel: 5% acrylamide, 0.13% Bis, 0.067 mol L ⁻¹ Tris-HCl, pH 6.8, 0.1% SDS, 0.067% ammonium persulfate and 0.067% TEMED; separation gel: 0.45 mol L ⁻¹ Tris-HCl, pH 6.9, 0.1% SDS, 0.05% ammonium persulfate, 0.05% TEMED, 7 mol L ⁻¹ urea	0.05 mol L ⁻¹ Tris, 0.38 mol L ⁻¹ glycine, 0.1% SDS, pH 8.5	log M_r vs. D (1400–17 000)	Hashimoto <i>et al.</i> (1983), Laemmli (1970)

M_r (Da), mol mass; D (mm), migration distance; TEMED, *N,N,N',N'*-tetramethylethylenediamine. The buffer solution containing 10% acrylamide (0.5% Bis) contains no sucrose while the buffer solution containing 18% acrylamide (0.9% Bis) contains 10% (w/v) of sucrose. The PAA concentration and the sucrose concentration increase linearly from top to bottom. The system can also be used to separate lipopolysaccharides and phospholipids. The addition of iodoacetamide to samples prior to electrophoresis eliminated artifacts currently observed in silver staining of protein bands. Log M_r correlates linearly with migration distance (D (mm)) in the mon mass range of 1.4 (kDa) to 17 (kDa). Flat gels of the dimensions 150 × 140 (height) × 1 (mm) were used. Gels were run for at least 15 h at 120 V. Samples were heated for 2 min at 100°C in a sample buffer containing 10% sucrose, 0.0625 M Tris-HCl, pH 6.8, 2% SDS, 10 mM dithiothreitol and 0.0025% Bromophenol blue (if necessary they were treated with iodoacetamide). Reproduced with permission from Rothe and Maurer (1986).

Diagnosis of the following proteinurias is possible:

1. Proteinuria in the normal range of total protein
2. Orthostatic (postural) proteinuria
3. Post-renal proteinurias
 - (a) Post-renal haematuria
 - (b) Local excretion of proteins
4. Bence-Jones proteinuria
5. Lower and upper urinary tract infections: cystitis and pyelonephritis
6. Diabetes mellitus

Concluding Remarks

Gradient gel electrophoresis has many advantages over conventional gel electrophoresis. Gradient range and course can be adapted to any individual separation problem, and protein bands are much sharper than in Cellogel or starch gel electrophoresis. So far, for example, more than 20 enzyme bands of an enzyme system such as plant acid phosphatase have been clearly resolved and genetically interpreted, and crude enzyme extracts can be used as the enzyme source, provided a specific detection (staining) system is available. The disadvantages are few compared to conventional gel electrophoresis, such as availability of gradient gel, a load of two to three times more enzyme activity per cm² of gel cross-section as compared to starch gels, and the exclusive migration of proteins towards the cathode (anode), whereas in Cellogel and starch gel electrophoresis both cathodically and anodically migrating proteins can be detected within the matrix.

Figure 16 Separation of urinary proteins by macro SDS PA gradient gel electrophoresis. Gel: 4–20% *T*. Running conditions: 3 h at 350 V, 50 mA. Samples: up to 50 μ L urine. (A) and (B) show urine samples from paediatric patients with pyelonephritis at various stages of follow-up. Series A: 1, acute phase; 2, and 3, urine taken at weekly intervals; 4, reinfection (acute phase); 5, 1 week follow-up. Series B: 1, acute phase; 2–4, follow-up at weekly intervals (note blood contamination in 2 and 3, α - and β -globin chains at 16 kDa), 5, reinfection, 6, and 7, weekly follow-up. Black dot and vertical arrow on the right side of the gel represent the application point and migration direction, respectively. + Gel polarity. Alb., albumin. Reproduced with permission from Bianchi-Bosisio *et al.* (1991).

In addition to pure PA gels, matrices of mixed polymers can be used for porosity gradients. However, this possibility has been rarely used, although it could extend the separation possibilities.

PA gradients are widely used to determine the molecular mass of SDS-denatured proteins, because this method offers a larger separation range and a much better resolution of protein bands. However, native, time-dependent PA gradient gel electrophoresis has much more possibilities to offer, such as differentiation between size and charge isomers, determination of the molecular size of native proteins and (iso)enzymes (M_r , R_s), estimation of the molecular excentricity (f/f_o), and calculation of the net negative charge at a given pH value. Using these possibilities the evolution of homologous proteins in related animal and plant species can be studied as well as the net charge of isozymes from different cells compartments.

Introduction

After polyacrylamide gel electrophoresis, it is essential that separated protein zones be detected for subsequent analysis, whether this is to be done by simple visual inspection or by quantitative computerized densitometry. In the early days of electrophoresis, methods for the detection of separated zones (ultra-violet absorption, Schlieren optics) were limited and insensitive. The subsequent development of organic dyes able to react with proteins made stains such as Bromophenol Blue and Amido Black 10B popular. In particular, Coomassie Brilliant Blue was for many years the method of choice for protein detection following gel electrophoresis owing to its relatively high sensitivity. However, the need for increased sensitivity resulted in the development of a group of staining methods based on the use of silver (approximately 0.1 ng of protein per band). Recently, there has been a renewed interest in the use of fluorescent methods of protein detection as they provide high sensitivity equivalent to silver staining combined with excellent linearity and extended dynamic range. Detection methods based on the use of radiolabelling also provide high sensitivity but cannot be applied in all situations. Finally, methods are available for the detection of groups of proteins with specific post-translational modifications, for example glycoproteins, phosphoproteins and lipoproteins.

Fixation

After electrophoresis is complete, the gel is removed from the apparatus for localization of the separated zones. Procedures have been described for the direct visualization of unfixed proteins within gels. How-

ever, for the majority of protein detection methods it is necessary to precipitate and immobilize (i.e. 'fix') the separated proteins within the gel and to remove any nonprotein components which might interfere with subsequent staining. Gels that are to be used for visualization of enzymatic activity of the separated proteins must not be fixed. The best general purpose fixative is 20% w/v trichloroacetic acid (TCA) as it gives effective precipitation of most proteins. Acid methanol (or ethanol), typically a solution containing 10% v/v acetic acid, 45% v/v methanol, and 45% deionized water, is often used for gel fixation, but it should be noted that this can be ineffective for small proteins, basic proteins and glycoproteins. Aqueous solutions of reagents such as 5% w/v formaldehyde or 2% w/v glutaraldehyde can be used to cross-link proteins covalently to the gel matrix, but this is not a commonly used approach.

Coomassie Brilliant Blue

The most popular general protein-staining procedures following gel electrophoresis are based on the use of the non-polar, sulfated triphenylmethane Coomassie stains, developed for the textile industry, Coomassie Brilliant Blue (CBB) R-250 is most often used and requires an acidic medium for electrostatic interaction between the dye molecules and the amino groups of proteins. Staining is usually carried out using 0.1% w/v CBB R-250 in the same acid methanol solution used for fixation (10% acetic acid, 45% methanol). Depending on gel thickness and polyacrylamide concentration, staining can take from 30 min to several hours. In practice, it is often convenient to stain the gel overnight and then destain it by several changes in the same acid methanol solution until intense blue protein zones can be seen against a clear background. This method is able to detect a minimum of around 100 ng protein per band (**Figure 1**), so that for complex mixtures containing several hundred components, it is necessary to load relatively high amounts of total protein (> 50 µg).

Figure 1 SDS-PAGE separation of human heart proteins (lanes b–g). Lane (a) contains the molecular weight marker proteins and the scale at the left indicates protein size in kDa. The gel has been stained with Coomassie Brilliant Blue R-250. The sample protein loadings were (b) 1 µg, (c) 5 µg, (d) 10 µg, (e) 25 µg, (f) 50 µg, (g) 100 µg.

More sensitive staining (down to 10 ng protein per band) can be achieved using the dimethylated form of the dye, CBB G-250, as a 0.1% w/v colloidal dispersion in 2% w/v phosphoric acid, 10% w/v ammonium sulfate, and 20% v/v methanol. An additional advantage of this method is that the colloidal dye only binds to the separated proteins as it is unable to penetrate the gel matrix. This means that no destaining step is required and the intensity of staining can be controlled by visual inspection during the staining process. Related dyes such as Acid Violet 17, Serva Violet 49 and Fast Green FCF also form colloids in strongly acidic solutions and stain proteins in gels with low background.

Silver Staining

Silver has been known to be able to develop images for over two hundred years, first being usefully exploited in photography and then rapidly adopted for use in histological staining procedures. The ability of silver to detect proteins following their separation by gel electrophoresis was first recognized by Merrill and his colleagues in 1979. Subsequently, more than a hundred silver-staining procedures have been described and this group of methods has become the standard approach for the sensitive detection of gel-separated proteins. However, certain classes of proteins, such as calcium-binding proteins and glycoproteins, stain rather poorly, with an inverse relationship

between the intensity of silver staining and the proportion of the molecule that is composed of carbohydrate. Pre-staining with cationic dyes prior to silver staining can significantly improve the sensitivity of detection of glycoproteins.

Depending on the method, silver staining is between ten and a hundred times more sensitive than staining with CBB R-250, and is able to detect low nanogram amounts of protein. There can be problems in using silver staining as a quantitative procedure as it is known to be non-stoichiometric. However, staining intensity is linear over a 40-fold range, comparing well with the 20-fold linear range of CBB R-250. Above this limit, the stain becomes non-linear, resulting in saturation and even negative staining of bands and spots at very high protein concentrations, making quantitation of such protein zones impossible. In a two-dimensional electrophoresis study of human leukocyte proteins, over 200 spots were observed to have coefficients of variation less than or equal to 15% when data from replicate patterns were analysed. In dilution experiments, the majority (> 80%) of the proteins were found to have a linear relationship between the amount of protein loaded and the spot volume. An additional problem with the quantitation of silver staining is that the relationship between staining intensity and protein concentration may be different for each protein. However, it is often forgotten that this is also the case for staining with CBB R-250.

All silver-staining procedures depend on the reduction of ionic silver to its metallic form, but the precise mechanism involved in the staining of proteins has not been fully established. It has been proposed that silver cations complex with protein amino groups, particularly the ϵ -amino group of lysine, and with sulfur residues of cysteine and methionine. However, staining cannot be attributed exclusively to specific amino groups suggesting that some other component of protein structure is also responsible for differential protein staining.

Procedures for silver staining can be grouped into two main types depending on the chemical state of the silver when used for impregnating the gel. The first group comprises alkaline methods based on the use of ammoniacal silver or diamine solution, prepared by adding silver nitrate to sodium-ammonium hydroxide mixture. Copper can be included in these diamine methods to give increased sensitivity, probably by a mechanism similar to the Biuret reaction. The silver ions complexed to proteins in the gel are then developed by reduction to metallic silver with formaldehyde in an acidified environment, usually using citric acid. In the alternative group of methods, silver nitrate in a weakly acidic (around pH 6.0)

solution is used for gel impregnation. Development is subsequently achieved by the selective reduction of ionic silver to metallic silver by formaldehyde made alkaline with either sodium carbonate or sodium hydroxide. Any free silver is washed out of the gel prior to development to prevent precipitation of silver oxide that would result in high background staining.

The majority of silver staining procedures are monochromatic, resulting in dark brown to black protein zones. However, if the development time is extended with saturation of the zones of highest protein concentration, then colour effects can be produced. In a comparative study of several methods based on both the silver diamine and silver nitrate approaches, the most rapid procedures were found to be generally less sensitive than those which were more time-consuming. The use of glutaraldehyde pre-treatment of the gel and silver diamine as the silvering agent were found to be the most sensitive and example of a gel stained with a method of this type is shown in **Figure 2**.

Increasingly, proteins are being visualized in gels for subsequent identification and characterization by techniques such as mass spectrometry. In this case, glutaraldehyde cannot be used and silver-staining protocols that omit this reagent must be used. However, this modification results in a decrease in sensitivity and uniformity of staining as well as an increase in background.

It is a common experience that silver-staining procedures can give rise to problems when based on the

use of laboratory-prepared reagents. If care is not taken with the use of high-purity water, reagents and glassware, then problems of high background staining, surface 'mirror' effects and poor reproducibility can be experienced. Many of these problems can be alleviated using one of the commercially available silver-staining kits (for example from Amersham-Pharmacia Biotech, Bio-Rad Laboratories, Richmond, CA, USA).

Reverse Stains

One disadvantage of the standard protocols for staining with Coomassie Blue dyes and silver is that it is essential to use a fixation step prior to staining. Unfortunately, this can result in reduced recovery of proteins from the gel for subsequent chemical characterization. Reverse stains have been developed to specifically overcome this problem. The result of these stains is a semi-opaque background on the gel surface, while the proteins are visible as transparent zones using back-lighting. The process of staining is rapid, requiring generally between 5 and 15 min. After staining, the proteins can be eluted after chelation of the metal ions with agents such as EDTA. It should be noted that reverse stains are not suitable for quantitative applications.

A variety of reverse-stain methods suitable for visualizing proteins after SDS-PAGE have been described. The most popular methods have been those using potassium chloride, copper chloride and zinc chloride, with the last being the most sensitive. The zinc imidazole-staining method is quite sensitive, with a limit of detection of around 10 ng protein per band. In the presence of imidazole, free or weakly bound zinc ions are readily precipitated as zinc imidazole, while tightly bound ions associated with proteins do not precipitate. This results in clear protein zones on an opaque background.

Fluorescent Detection Methods

Many of the problems inherent in the quantification of gel-separated proteins visualized by silver staining can be overcome using detection methods based on the use of fluorescent compounds. This group of methods is highly sensitive and generally exhibits excellent linearity and a high dynamic range, making it possible to achieve good quantitative analysis, particularly if a suitable imaging device is used.

Two approaches can be used, the first being to couple the proteins with a fluorescent-labelled compound prior to electrophoresis. Examples of such compounds are: dansyl chloride; fluorescamine (4-phenyl-[furan-2(3H)-1-phthalan]-3,3'-dione);

Figure 2 SDS-PAGE separation of human heart proteins (lanes b–g). Lane (a) contains the molecular weight marker proteins and the scale at the left indicates protein size in kDa. The gel has been silver stained. The sample protein loadings were (b) 1 µg, (c) 5 µg, (d) 10 µg, (e) 25 µg, (f) 50 µg, (g) 100 µg.

o-phthaldialdehyde (OPA) + a thiol; and MDPF (2-methoxy-2,4-diphenyl-3(2H)-furanone). The last reagent has a reported sensitivity of 1 ng protein per band and is linear over the range 1–500 ng protein per band.

The main disadvantage of pre-electrophoretic staining procedures is that they can cause protein-charge modifications, for example fluorescamine converts an amino group to a carboxyl group when it reacts with proteins. Such modifications usually do not compromise SDS-PAGE unless a large number of additional charged groups are introduced into the protein. However, they result in altered mobility during other forms of electrophoresis, giving rise to altered separations by native PAGE, IEF and two-dimensional electrophoresis. Recently, compounds that react with cysteine or lysine residues have been described and used successfully for two-dimensional electrophoresis separations. The cysteine-reactive reagent monobromobimane has been used to label proteins prior to analysis by two-dimensional electrophoresis. Using a cooled CCD camera to measure fluorescence, the limit of detection was found to be 1 pg protein per spot.

In an alternative approach, two amine-reactive dyes (propyl Cy3 and methyl Cy5) have been synthesized and used to label *Escherichia coli* proteins prior to electrophoresis. These cyanine dyes have an inherent positive charge, which preserves the overall charge of the proteins after dye coupling. The two dyes have sufficiently different fluorescence spectra that they can be distinguished when they are present together. This allowed two different protein samples, each labelled with one of the dyes, to be mixed together and subjected to two-dimensional electrophoresis on the same gel. This method, which has been termed 'difference gel electrophoresis (DIGE)', has great potential for improving the efficiency of detection of differences in two-dimensional electrophoresis protein profiles between different samples.

For two-dimensional electrophoresis, one approach to overcoming the problems associated with charge modification during the IEF dimension is to label the proteins while present in the first dimension gel after IEF, prior to the second dimension separation by SDS-PAGE. Two fluorescent labels that have been used in this way are MDPF and a fluorescent maleimide derivative.

The alternative approach, which also overcomes the problem of protein-charge modifications, is to label the proteins with fluorescent molecules such as 1-aniline-8-naphthalenesulfonate (ANS) and OPA after the electrophoretic separation has been completed. However, these two methods suffer the disadvantage of relative insensitivity. Recently, two post-

electrophoretic fluorescence staining reagents, SYPRO orange and red (Molecular Probes, Eugene, Oregon, USA), have been described. These stains have a very high sensitivity (1–2 ng protein per band) and excellent linearity with a high dynamic range. Using a fluorescence imaging device, the SYPRO dyes have been shown to be linear over three orders of magnitude in protein quantity. The other advantage of this method is that staining can be achieved in only 30 min, compared with staining with silver and CBB R-250 which can take from 2 h to overnight. Gels can be stained without fixation so that they can be subjected to subsequent Western blotting procedures. However, staining with these reagents requires that the proteins are complexed with SDS, so that if the gels are fixed prior to staining or electrophoresis is carried out in the absence of this detergent, then the gels must be incubated in a solution of SDS prior to staining. An SDS-PAGE gel separation visualized using SYPRO red is shown in Figure 3.

Metal Chelate Stains

This recently developed group of stains have been developed specifically for compatibility with characterization methods such as mass spectrometry as they do not use reagents such as glutaraldehyde or formaldehyde which reduce their efficacy. Although a stain of this type, using the pink bathophenanthroline disulfonate/ferrous complex, was described over twenty

Figure 3 SDS-PAGE separation of human heart proteins (lanes b–g). Lane (a) contains the molecular weight marker proteins and the scale at the left indicates protein size in kDa. The gel has been stained with SYPRO red. The sample protein loadings were (b) 1 µg, (c) 5 µg, (d) 10 µg, (e) 25 µg, (f) 50 µg, (g) 100 µg.

years ago, its insensitivity (600 ng protein) ensured its lack of acceptance. Sensitivity can be increased by introducing ^{59}Fe into the complex, but only to a level equivalent of colloidal Coomassie Blue staining.

The poor performance of these dyes resulted in a recent investigation of luminescent metal chelate stains. Such stains utilizing metal chelates complexed to certain transition metal ions (e.g. europium, terbium, and ruthenium) offer much greater sensitivity compared to the previous colorimetric methods. Of particular interest is SYPRO Ruby, a proprietary ruthenium-based metal chelate stain (Molecular Probes, Eugene, Oregon, USA). This allows one-step, low background staining of proteins in polyacrylamide gels without resorting to lengthy destaining procedures. The linear dynamic range of this dye extends over three orders of magnitude, thus surpassing silver and Coomassie stains in performance. Its sensitivity is claimed to be up to thirty times more sensitive than silver staining. Moreover, staining times (unlike silver protocols) are not critical and staining can be carried out overnight without overdevelopment.

Radioactive Detection Methods

Metabolic labelling of proteins with a radiolabelled amino acid prior to their separation by gel electrophoresis represents a very sensitive method for the detection of proteins and is ideal for the analysis of protein synthetic events occurring in response to an experimental intervention. This approach is most commonly used in combination with *in vitro* cell culture systems, but it is also possible to radiolabel synthetically the proteins of small pieces of fresh tissue in this way. In this method, the cells or tissue are incubated in the presence of the radiolabelled amino acid for a period of time, normally between 3 and 24 h. It is important to use a tissue culture medium that has been depleted of the amino acid used for radiolabelling. The most commonly used amino acids for radiolabelling are [^{35}S]-methionine and [^{14}C]-leucine. [^3H]-amino acids can be used, but these are more difficult to detect due to the weak energy of their beta emissions. Methods are also available for synthetic radiolabelling to detect specific post-translational modifications of proteins.

Proteins can also be radiolabelled post-synthetically, prior to their separation by gel electrophoresis, using a variety of methods such as radioiodination with ^{125}I or reductive methylation with [^3H]-sodium borohydride. However, most of these methods result in significant charge modification of the target proteins, generally precluding their use for electrophoretic techniques other than SDS-PAGE.

Following electrophoresis of radiolabelled proteins, the gel must normally be dried prior to detection of the radioactive zones. Thin gels cast on plastic supports can be dried, after equilibration in 3% w/v glycerol, in air or in an oven at 40–50°C. It is also possible to air-dry gels which have not been cast on supports. These should be equilibrated in 3% w/v glycerol and placed between two cellophane sheets supported in a plastic frame. The gels are then dried in hot air at 40–50°C; the process usually taking 2 or 3 h. The best method for drying gels which are not on supports is by heating them under vacuum. Gels should be soaked in 3% w/v glycerol prior to drying. Gradient polyacrylamide gels are particularly prone to cracking and these can be protected by soaking in a solution containing 1% w/v glycerol and 2% v/v dimethyl sulfoxide (DMSO). Gels can be dried down onto filter paper or onto cellophane. A temperature of 80°C is normally used, but it is better to use a lower temperature (40–60°C) for gels at risk of cracking (i.e. thick, high percentage or gradient gels).

Radiolabelled proteins are most easily detected by direct autoradiography, in which the dried gel is placed in contact with X-ray film and exposed for the appropriate time. This method works satisfactorily for isotopes such as ^{14}C , ^{35}S , ^{32}P and ^{125}I , but is not suitable for ^3H owing to its low-energy beta-emissions which are not able to penetrate the gel matrix. Much sensitive detection can be achieved using fluorography in which the gel is impregnated with a scintillant, such that low-energy beta particles excite the fluor molecules to emit photons which can be detected on a suitable (usually blue-sensitive) X-ray film. In the original procedure, 2,5-diphenyloxazole (PPO) which must be dissolved in DMSO, was used. However, fluorography with commercially available enhancers is simpler and less tedious than the original PO-DMSO method, and produces equivalent results. Pre-exposure of the X-ray film to a brief flash of light (approximately 1 ms) increases the sensitivity of fluorography by two- or threefold. The use of an intensifying screen and exposure at low temperature (–70°C) also result in a significant increase in sensitivity.

Techniques of autoradiography and fluorography are simple and require little specialized equipment, apart from the access to darkroom facilities. However, prolonged exposure times are often required to achieve the desired level of sensitivity of protein detection. Moreover, the nonlinear response of X-ray film and its limited dynamic range present severe problems to accurate quantitation. To overcome these problems several devices for detecting radiolabelled proteins directly in gels have been described. The best and most practical of these

approaches are imaging devices based on the use of photostimulable storage phosphor-imaging screens.

Detection of Specific Biological Compounds

Detection of Glycoproteins

Proteins with limited glycosylation can be detected following gel electrophoresis with the general protein stains such as CBB R-250 and silver. However, such staining gives no direct indication that these proteins are glycosylated and the methods are much less sensitive if the proteins are more highly glycosylated. Proteoglycans are usually stained with cationic dyes, such as Alcian Blue or Toluidine Blue, which bind to the negatively charged glycosaminoglycan side chains. Glycoproteins have generally been detected using variations of the Schiff base reaction, involving oxidation with periodic acid followed by staining with Schiff reagent, Alcian Blue or a hydrazine derivative. A twofold increase in sensitivity can be achieved with methods in which Alcian Blue is used as the primary staining agent followed by subsequent enhancement using a neutral silver-staining protocol.

An alternative approach to the analysis of glycosylated proteins is to radiolabel then *in vitro*, followed by gel electrophoretic separation of the radiolabelled proteins and their detection. N-linked sugar labelling can be achieved using [³H]-mannose and terminal O-linked N-acetylglucosamine can be labelled by galactosyltransferase and UDP-[³H]-galactose.

Probably the most versatile reagents for the characterization of glycosylated proteins following their separation by electrophoresis are radiolabelled, fluorescent or enzyme-conjugated lectins. Although it is possible to use these directly in the gel matrix, much better results are achieved using Western blotting techniques.

Detection of Phosphoproteins

The most commonly used approach to the analysis of protein phosphorylation is to radiolabel cells in culture with either [³²P]-orthophosphate or [γ -³²P]-ATP. An alternative approach, which avoids the use of radioactive materials, is to use antibodies which are specific to phosphotyrosine, phosphothreonine and phosphoserine in combination with Western immunoblotting.

Detection of Lipoproteins

Lipoproteins can be stained following electrophoresis with Sudan black B. Prenylated proteins can be

radiolabelled prior to electrophoresis with [³H]-mevalonolactone, while fatty acylated proteins can be radiolabelled with [³H]-palmitic or [³H]-myristic acid.

Detection of Enzymes

It is generally considered that specific enzyme activities can only be visualized following gel electrophoresis if native conditions have been used. However, there are several reports demonstrating that SDS-denatured proteins can also be visualized provided that it is possible to achieve at least partial renaturation of their spatial configuration. Such renaturation is most effective if disulfide bonds are not essential for enzymic activity and if the native protein is not composed of subunits of different molecular weights. Pre-electrophoresis of gels is usually recommended to remove unreacted acrylamide monomers and catalysts.

Enzyme staining can be achieved by incubating the unfixed gel in a solution of the appropriate reagents using either fluorogenic or chromogenic substrates. This method works well if the final reaction product is insoluble. However, a soluble reaction product will rapidly diffuse resulting in loss of resolution. It is generally preferable to use a print or gel overlay technique. In this approach, the substrates and other reagents are either impregnated into a filter or included in a thin layer of agarose or polyacrylamide gel cast on a glass or plastic support. The overlay is then placed in direct contact with the surface of the separation gel and following a suitable period of incubation, the enzymic activity is visualized on the overlay. Methods are available for the visualization of a large number of enzyme activities following gel electrophoresis.

Principles

Electrophoresis is a very separation technique which involves the separation of charged species (molecules) on the basis of their movement under the influence of an applied electric field. It is widely used by chemists and biochemists in studies related to medical technology, environmental research, food and water analysis, pollution control and forensic investigations. The development and applications of electrophoretic separation methods are an example of the fruitfulness of using physical methods in tackling biological and biochemical problems.

The migration of charged colloidal particles in an electric field was originally given the name cataphoresis or electrophoresis. Because there has been some diversity of opinion about the definition of a colloid, and thus about the distinction between colloidal and molecular systems, there has also been some differ-

ence of opinion as to how widely the term ‘electrophoresis’ should be used. Some authors prefer the term ionophoresis to describe the movement of relatively small molecules or ions under such conditions.

The 1940s and 1950s witnessed very rapid developments in the applications of methods making use of the migration of particles in an electric field. These applications covered the whole range of particle sizes from the largest protein molecules to small molecules like amino acids, sugars (at high pH) and even simple inorganic ions, using the sample types of procedures and apparatus. Although it is not a form of chromatography, the differences in the rates of migration of the charged particles provide a powerful means of separating biocolloids such as proteins, polysaccharides and nucleic acids, as well as for the characterization of their components. For these reasons, and also for historical reasons, it is now general practice to use the term ‘electrophoresis’ to refer to all these procedures. Electrophoresis pertains to the transport of electrically charged particles – ions, colloids, macromolecular ions or particulate matter – in an electric field.

Electrophoresis experiments are usually carried out to obtain information on the electrical double layers surrounding the mobile particles, to analyse a mixture, or to separate it into components. Interpretation of experimental results requires a theory connecting the electrophoretic mobility with the fundamental quantities relating to the electric double layer – the electrical potential, charge and structure.

The electrical double layer is not restricted to the interface between electrically conducting phases. For example, if a glass rod is immersed in an aqueous electrolyte, then it will carry a double layer of ions wholly within the electrolyte phase. This double layer originates from the specific adsorption of a Helmholtz layer of anions or cations from solution onto the glass surface. The resulting excess of charge is neutralized by a diffuse or Gouy layer dispersed further out in the solution. If we consider the case of two insulating phases, namely glass and oil, the double layer at the interface may be considered to arise either from the specific adsorption of ions generated by very weak electrolytes or from the orientation of dipolar molecules. The behaviour of the diffuse or mobile component of the double layer may be correlated with a class of phenomena which includes electrokinetic effects.

Electrokinetic effects are associated with the relationship between the relative motion of two phases (generally a liquid and a solid) and the electrical properties of the interface between them. Electrokinetic phenomena arise in microheterogeneous systems, i.e. in cases when one phase is dispersed in another. Electrokinetic effects may be classified into four groups: (1) electroosmosis, (2) electrophoresis, (3) streaming potential and (4) sedimentation potential.

1. *Electroosmosis* is the movement of a liquid along a capillary, a system of capillaries or a porous plug under the influence of an externally applied electric field.
2. *Electrophoresis* is the movement of solid particles under the influence of an electric field applied to the medium in which the particles are suspended. In this case the disturbance of the double layers attached to the solid moving particles produces the effect. It may be regarded as the reverse of electroosmosis, in which the solid phase is fixed and it is the movement of the liquid phase that is induced by the applied electric field. In both electrophoresis and electroosmosis the applied potential difference sets up a mechanical force which results in the movement of one phase.
3. *Streaming potential* is the building up of potential difference between the upstream and downstream

ends of liquid flow. This is caused by friction between the moving liquid layer and the wall of the capillary, the system of capillaries or the porous plug.

4. *Sedimentation potential* (Dorn effect) is the converse of electrophoresis and results in the building up of potential difference between the top and the bottom of a vessel in which dispersed solid particles are suspended in a liquid.

The theoretical treatment of the electrical double layer depends on its geometry. The double layer at a flat interface constitutes the most simple case, which we can analyse to explain many of the facts connected with double layers. The boundary between two phases is a layer of finite dimensions. The properties of the two adjacent phases change gradually over a certain distance. These changes depend both on geometrical factors and on the forces between the molecules. The density and orientation of the molecules, even in a one-component system, undergo a gradual change when going from one phase to another, e.g. from the liquid to the gas phase. In multicomponent systems the boundary layer concentrations are different from those in the bulk, leading to what is called adsorption. Though these changes near phase boundaries are limited to only a very few layers of molecules, all the properties of the phases are changed in this transition layer.

When one or both phases contain ions, the transition layer may be much more extended. In such a case, one type of ion is strongly concentrated at the phase boundary by short-range forces. When ions of one sign are adsorbed at the phase boundary, ions of the opposite sign will be attracted by the resulting electric field and will accumulate near the phase boundary. This accumulation is opposed by their Brownian movement. As a result an electrically neutral double layer is formed which may extend to a considerable thickness (a few tens of nanometres).

In order to apply simple mathematical treatment to electrokinetic phenomena it is assumed that the diffused double layer acts as a parallel plate electric capacitor whose plates are d cm apart, each carrying a charge e per cm^2 . The zeta potential, i.e. ζ , the potential difference between the plates, is given by eqn [1]:

$$\zeta = 4\pi ed/D \quad [1]$$

where D is the dielectric constant of the medium between the hypothetical plates. This is the fundamental equation for the quantitative treatment of all types of electrokinetic phenomena.

When a liquid is forced by electroosmosis through the fine capillaries of a porous diaphragm, two opposing factors will determine the flow, namely the force of electroosmosis and the frictional force between the moving liquid layers and the capillary wall. When the two forces become equal, the flow attains a uniform rate. If u is the uniform velocity so obtained and d is the effective thickness of the double layer across which the flow takes place, then the velocity gradient in the double layer may be taken as equal to u/d . Since the velocity at one side, i.e. the wall, is zero, and the average value on the other side, i.e. in the moving liquid, is u , the force due to frictional effects is equal to $\eta u/d$, where η is the coefficient of viscosity of the liquid. If E is the potential gradient across the membrane and e is the charge per cm^2 at the boundary of movement, then the electrical force causing electroosmosis is equal to Ee . Hence at the steady state eqn [2] applies:

$$Ee = \eta u/d \quad [2]$$

Substituting the value for d from eqn [2] in eqn [1] we obtain eqn [3]:

$$\zeta = 4\pi\eta u/DE \quad [3]$$

Following on from this discussion of electrokinetic phenomena, electrophoresis takes place due to the presence of an electrical double layer at the interface between the dispersed phase and the dispersion medium, and the consequent presence of a zeta potential. On applying an external electromotive force, positive and negative portions of the double layer are displaced relative to each other. Since the particles in a solution are free to move, they will migrate under the influence of the applied electric field. As has been noted previously, the double layer surrounding a particle may be treated as a capacitor. We can therefore derive a relationship for the observed velocity u' of the particle from eqn [3], namely eqn [4]:

$$u' = \zeta DE/4\pi\eta \quad [4]$$

Here the quantity $u'/E = U$ represents the particle's mobility, i.e. the velocity for a potential gradient of 1 V cm^{-1} .

Consider the case of a comparatively large spherical particle of radius R carrying a charge q in a medium of dielectric constant D . According to electrokinetic theory the potential of the particle may be given by q/DR . If the charge is identified with that present in the diffused double layer only, then the potential is ζ and since the thickness of the Helm-

holtz double layer is negligible compared with the radius of large particles, R may be taken as equal to the radius of particle plus its Helmholtz layer. This can be written as shown in eqn [5]:

$$\zeta = q/DR \quad [5]$$

From eqns [4] and [5] we get eqns [6] and [7]:

$$u' = qE/4\pi\eta R \quad [6]$$

$$U = q/4\pi\eta R \quad [7]$$

where U is the electrophoretic mobility. If the surrounding medium is an electrolyte, the interaction between the charged and migrating particles will reduce the zeta potential, ζ , of the particle. The magnitude of this effect has been evaluated by Debye and Hückel, who observed that ζ is reduced by a factor of $1/(1 + KR)$, where $1/K$ is ionic length. K is of the order of 10^{-7} – 10^{-8} cm and can be calculated in terms of ionic charges in the electrolyte, the concentration and dielectric constant of the electrolyte and the radius at which the ionic atmosphere would need to be concentrated to obtain the potential of the ion. The electrophoretic mobility for a comparatively large spherical particle in an electrolyte may be given by eqn [8]:

$$U = \left(\frac{q}{4\pi\eta R} \right) \left(\frac{1}{1 + KR} \right) \quad [8]$$

Eqn [8] is not applicable to small spherical particles where the curvature of the double layer is too large for streaming to take place entirely in the direction of the applied field. In such a case the electrical force on the particle is equal to the viscous drag as given by Stokes' law. Considering the effect of the electrolyte on the zeta potential (as in eqn [8]) the result for a small spherical particle is given by eqn [9]:

$$U = \left(\frac{q}{6\pi\eta R} \right) \left(\frac{1}{1 + KR} \right) \quad [9]$$

Debye and Hückel made an exact treatment and found that the factor 4 in eqn [8] is strictly only applicable for cylindrical particles, and it should be replaced by the factor 6 (as in eqn [9]) for spherical particles. Eqns [8] and [9] are thus the special cases of a general expression covering all sizes of particle. A slight modification can be made to eqn [9] to give the electrophoretic mobility according to:

$$U = \left(\frac{q}{4\pi\eta R} \right) \left(\frac{1}{1 + KR} \right) f(KR) \quad [10]$$

where $f(KR)$ is a complicated function of K and R . More elaborate equations for electrophoretic mobility have been derived by taking into account the finite sizes of ions in the double layer attached to the particle. Gorin has also given a treatment for cylindrical particles.

Looking at the consequences of the complications associated with the theoretical deviation of the relationship between the electrophoretic mobility and the shape of the particle, attempts have been made to solve the problem experimentally. However, the experimental results are equally inconclusive. Abramson established that the electrophoretic mobility is independent of the shape of the moving particles by performing experiments on the movement of spherical particles of some oils and of needles of asbestos and *m*-aminobenzoic acid coated with the same protein.

The applicability of eqns [8] and [9] (for spherical particles) can also be tested by the comparison of electroosmotic and electrophoretic mobilities using a microelectrophoresis cell made of the same material as the suspended particle, e.g. glass or quartz. If eqn [8] is correct, then the ratio of the two mobilities should be unity; on the other hand if eqn [9] is correct, the ratio should be 1.5. Experiments with spherical particles and surfaces, all coated with adsorbed protein to ensure that the surfaces were the same, indicated that the mobility ratio was approximately unity, as required by eqn [8]. Objections have been raised to this conclusion on the grounds that the independence of electrophoretic mobility with respect to the shape of particles and the value of unity for the mobility ratio were due to the use of a liquid medium containing a relatively high concentration of the electrolyte. The objectors stated that if the electrolyte concentration is less than 1 mmol L^{-1} then the ratio of electrophoretic to electroosmotic mobility is unity. Other workers also questioned the conclusion, and as such the situation is somewhat uncertain. However, eqn [8] may be regarded as reasonably adequate for particles of any shape.

Factors Affecting Electrophoretic Mobilities

Several factors have a definite influence on the electrophoretic mobilities of charged molecules or ions.

Nature of the Charged Molecule

The nett charge, size, shape and relative mass of particles has a great influence on their electrophoretic mobilities. The charge-to-size ratio of molecules is an important parameter. The higher its charge-to-size

ratio (e/r), the faster a molecule will migrate under given conditions.

Nature of the Electrophoretic System

As well as the characteristics of the substances to be separated, there are several parameters relating to the electrophoretic system itself that have a pronounced effect on the electrophoretic mobilities of the molecules or ions. These parameters are as follows.

1. The ionic composition of the electrophoresis buffer.
2. The temperature.
3. The pH of the electrophoresis buffer.
4. The applied voltage.
5. In the case of zone electrophoresis, the type of support medium chosen, and if the support medium is gel, its pore size.

Ionic composition of the electrophoresis buffer

A charged macromolecule becomes surrounded by an ionic atmosphere of opposite charges because of interactions between ionizable groups on the surface of the charged molecule and ions in the electrophoresis buffer. As a result, both its net charge and its electrophoretic mobility are decreased. This effect is quite pronounced in the electrophoretic separation of proteins, since different proteins have different amino acid side chains which interact to varying degrees with the ions in the solutions used.

In order to minimize these 'counterion' effects it is advisable to use an electrophoresis buffer with as low an ionic strength as possible. However in some cases, such as with polypeptides and polynucleotides, electrophoresis has to be carried out in solutions of high ionic strength, otherwise these macromolecules will not be soluble. It therefore becomes necessary to choose a suitable salt concentration.

Temperature Temperature plays a pronounced effect on electrophoresis. In an electrophoretic run, heat (Joule's heat) is generated and may affect the electrophoresis in a number of ways.

1. *Diffusion*. An increase in temperature causes an increase in the diffusion of migration zones of charged molecules. If the electrophoresis takes a long time (several hours) diffusion effects become more significant.
2. *Evaporation*. It is customary to perform electrophoresis in a closed system to avoid loss of water by evaporation, which increases with temperature. This evaporation results in the drying out of the supporting medium and also leads to an

increase in the ionic strength of the buffer during the analysis.

3. *Viscosity.* In gel electrophoresis an increase in temperature can change the viscosity of the medium. Since this takes place during the electrophoretic run, the interpretation of the results may become complex.
4. *Distortion of zones.* During an electrophoretic run, particularly in column gels if cooling is inadequate, the portions of the migration zones in the warmer parts of the gel move faster than those in the cooler parts. This difference in migration speeds produces curved bands. This may result in the overlap of neighbouring zones and consequently in poor resolution.
5. *Convection currents.* During an electrophoretic run the warmer solution in the centre of the apparatus has a lower density than the cooler solution close to the walls. This density gradient induces convection currents in the solution. Since water has its maximum density at 4°C, and the smallest variations in density of aqueous solutions are observed around this temperature, it is advisable to perform electrophoresis at a temperature as close as possible to 4°C. However, the viscosity of an aqueous solution increases as the temperature is lowered, which may result in an increase in the frictional resistance to the migration of the charged molecules. If the temperature is maintained at 4°C the electrophoretic mobilities of the charged molecules will be relatively low. It is therefore necessary to choose an optimal temperature for a particular electrophoretic run and maintain it throughout the course of analysis.

pH of the electrophoresis buffer pH has a marked effect on the nett charge on a protein molecule. At a definite pH value, i.e. at the isoelectric point, the nett charge on the molecular is zero. Molecules acquire a nett positive charge at pH values below their isoelectric points. At pH values above their isoelectric points, they acquire a nett negative charge. Thus different molecules (e.g. proteins) at any particular pH value will have different nett charges. To optimize the separation of a mixture of (protein) molecules the buffer pH must be chosen on the basis of the nett molecular charges. For example in an electrophoretic run two or more proteins may migrate together to give only one band. If the analysis is done at a different buffer pH value it may result in the appearance of extra protein bands, indicating the presence of other proteins in the sample.

Applied voltage In electrophoresis the applied voltage plays an important role. The migration velocity of

a molecule is proportional to the field strength across the medium. The higher the applied voltage, the larger the field strength across the medium, and the faster a molecule will migrate. Thus, the charged molecules will migrate more quickly with increasing voltage. This saves time and reduces the diffusion of migrating molecules. However, with increasing voltage the current also increases, resulting in greater power generation (the power increases as the square of the current).

Some of this power is dissipated as heat (Joule's heat). The heat generated can have serious effects on an electrophoretic analysis, as discussed previously. It is therefore necessary to select a definite value of applied voltage. The voltage (or current) should be large enough to allow rapid migration of charged molecules, but not so large as to generate excessive heat.

Support medium In zone electrophoresis different types of support media are used. The selection of the most suitable support medium for a particular zone electrophoretic analysis is based on the following considerations.

1. Sample quality.
2. Size of the molecules – whether they are small or large. If a sieving gel has to be used its pore size (concentration) is chosen so as to suit the molecular size under study.
3. The time required for analysis.

Types of Electrophoresis

Electrophoresis analysis can be divided into three main types, as listed here.

1. moving-boundary electrophoresis
2. zone electrophoresis
3. steady-state electrophoresis.

Moving-Boundary Electrophoresis

Moving-boundary or free solution electrophoresis was first proposed by Picton and Linde in 1892 and was fully developed by Tiselius in 1930, finding wide application between 1935 and the 1950s. Its principle use was in protein research, where it provided invaluable results.

The apparatus for moving-boundary electrophoresis, in its simplest form, consists of a U-tube with a rectangular cross-section (**Figure 1**). It is partially filled with the solution to be analysed (protein solution) and a buffer solution is layered over it. Electrodes are immersed in the buffer solution.

When an electromotive force is applied across these electrodes the charged molecules move towards the appropriate electrode. If the solution under study is

Figure 1 Apparatus for moving-boundary electrophoresis.

coloured and contains several components with different electrophoretic mobilities, then their migration can be observed as multiple moving boundaries in the system. Where the migration boundary is not visible to the naked eye it may be made visible by causing it to fluoresce as a result of exposure to ultraviolet (UV) light. In such a case the apparatus should be made of quartz. In the case of protein solutions which have a refractive index slightly greater than that of the buffer, there will be a change in refractive index at the protein boundary in the apparatus, which can be detected by optical methods.

After completion of the electrophoretic analysis the different fractions containing the components separated from the original sample can be analysed using appropriate methods.

Moving-boundary electrophoresis has proved to be useful in the determination of complex heterogeneous samples. However, it has a drawback in that only the slowest and fastest moving components of a sample can be obtained in pure form.

Zone Electrophoresis

Zone electrophoresis results in the complete separation of the components of a mixture in the form of discrete zones. The separated zones may be stabilized

in a number of ways which include the use of support media, density gradients and free zone techniques.

Use of support media An important development in electrophoresis was the use of support media for stabilizing zones of electrophoretically separated mixtures. A porous medium such as filter paper, cellulose acetate film, a gel, glass beads, granular starch or polyvinyl particles, etc., is used as the support medium. The separatory power of some of the gels exceeds that of other media or free solution.

The most common apparatus for zone electrophoresis using support media is depicted in **Figure 2**.

The sample is placed on the support medium in the form of a spot or narrow band at the sample origin. On subjecting it to electrophoresis the components of the sample separate into bands which are kept distinct by the presence of the support medium.

Zone electrophoresis in density gradients An important method that allows complete separation of complex mixtures involves carrying out electrophoresis in a density gradient column. The density gradients are usually solutions of substances such as ethylene glycol, glycerol, sucrose, etc., which do not ionize or interact with the materials under examination.

Free zone electrophoresis Although it is a complex technique, by using this method it is reasonably simple to recover the separated components at the end of analysis. The electrophoretic analysis may be performed in two ways, by rotation of the electrophoresis vessel during the run or by streaming a continuous film of buffer across the electrophoretic system, in a direction perpendicular to the applied electric field. These techniques are not in common use because they require elaborate equipment and are expensive.

Steady-State Electrophoresis

The fundamental basis of this method is that, after electrophoresis has proceeded for a certain length of

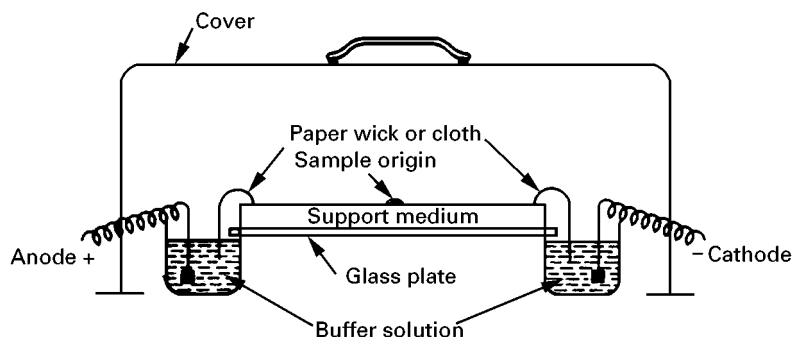

Figure 2 Apparatus for zone electrophoresis.

time, a state known as the steady-state is reached in which no further changes to either the position or the width of the zone of the separated components occur with time. Steady-state electrophoresis involves two types of techniques, isoelectric focusing and isotachophoresis.

Isoelectric focusing In this technique the charged components of the sample move through the medium under the influence of an applied electric field until they ultimately reach a position in the pH gradient where their net charge is zero and hence they do not migrate any more. This pH is their isoelectric point. The individual bands may be collected from the apparatus, and examined chemically or biologically.

This technique has very high resolving power, and may be used preparatively. It is not applicable to some compounds (proteins) that precipitate at their isoelectric point, which makes their recovery difficult.

Isotachophoresis This technique is particularly applicable to the separation of charged components with small relative molecular masses, such as some drugs and polypeptides of medical interest. In this technique all the charged components become stacked one behind the other, depending upon their electrophoretic mobilities.

To achieve a good separation of two charged components from one another by isotachophoresis, their electrophoretic mobilities must differ at least by 10%.

Comparison of Moving-Boundary and Zone Electrophoresis

In moving-boundary electrophoresis a differential movement of the charged particles towards one or the other of the electrodes is observed. Separation takes place as a result of differences in mobilities. The mobility of a particle is approximately proportional to its charge-to-mass ratio. However, this technique suffers from several disadvantages, one of the most serious being the tendency of the separated components to mix by convection as a consequence of thermal and density gradients and mechanical vibrations. Thus, careful thermal regulation and isolation from mechanical vibrations is essential. Also, elaborate optical systems are often required for locating and measuring the fraction, making this method quite expensive.

Many of these experimental difficulties associated with moving-boundary or free solution electrophoresis may be avoided if separations are carried out in a supporting medium (zone electrophoresis), such as

on paper. This prevents convection currents from distorting the electrophoretic pattern. This technique closely resembles the various chromatographic methods, with the additional parameter of a superimposed electric field. The separations mainly depend upon the properties of the medium and may result primarily from the electrophoretic effect or from a combination of electrophoresis and adsorption, ion exchange, or other distribution equilibria.

Practical Problems

The Joule's heat generated in an electrophoretic run causes various problems, including changes in the pH of the buffer medium, diffusion and distortion of the zones, and evaporation and convection currents. It should be remembered that these effects may occur simultaneously, which may complicate the results. It is therefore necessary to optimize the temperature for a particular analysis and keep it constant.

In paper electrophoresis there is liable to be variability in the quality of paper from batch to batch, and also perhaps within one sheet. Some papers have adsorptive properties that may affect the electrophoretic mobility of the molecules under study. Ionizable groups may produce an electroosmotic effect on the paper, which in turn may distort the migration characteristics of the separating components. The physical and chemical inhomogeneity of the support medium also has a pronounced effect on the migration of substances which in turn affects the results.

The method used for the detection of sample components separated by electrophoresis depends on the type of electrophoresis, the nature of the molecules to be detected, and the purpose of analysis. Some detection methods are listed in **Table 1**.

Separations using electrophoretic methods may not be adequate for very complex mixtures. Resolutions may be improved substantially by combining electrophoresis with some other separation technique. The sample subjected to electrophoresis in one direction while the other separation analysis is carried out in a perpendicular direction (so-called two-dimensional techniques).

Applications

Electrophoresis involves the separation of charged species on the basis of their movement under the influence of an applied electric field. It has found wide applications in the characterization of biological molecules (proteins and nucleic acids). The main applications of electrophoresis have been in the separation of biological molecules, which includes molecules with

relatively lower relative molecular masses such as amino acids, and also molecules of higher relative molecular masses such as proteins and polynucleotides (including RNA and DNA molecules). An example of the use of paper electrophoresis follows.

Paper electrophoresis has been extensively used in almost all laboratories where proteins and other similar macromolecular electrolytes are investigated. The apparatus (Figure 2) consists of two electrode chambers placed 15 cm apart. There is also a device which can support up to six (30 cm) filter paper strips between the electrodes. A d.c. supply source (0–250 V) is used to apply the desired voltage across the electrodes. The two electrode chambers are filled to equal heights with the buffer solution. The buffers commonly used for this purpose are (1) Aronsson and Gronwall buffer, i.e. dimethyl barbiturate buffer, which is a mixture of 20.60 g sodium dimethyl barbiturate and 2.80 g barbituric acid with a pH of 8.6, and (2) Consden and Powell buffer, i.e. borate buffer, which is a mixture of 1.77 g sodium hydroxide and 9.60 g orthoboric acid with a pH of 8.6.

Whatman paper (M540) strips (about 30 cm long) are cut and dipped in a container of buffer until they are thoroughly wet. The excess buffer is then removed by laying them out on a large sheet of filter paper. The strips are then immersed into the electrode chambers so that the ends of the strips dip in the buffer solutions. The sample is applied at the centre of the paper. The paper strips are allowed to stand for about 1 h, to equilibrate the bed with the liquid evenly throughout the paper. The power supply is then switched on and the voltage adjusted to about 75 V. Excellent sharply defined separations of serum proteins into five fractions within a span of 2 cm can be obtained within 1 h. If the run is extended to 16 h, a pattern approximately 12 cm long with five fractions may be obtained. On completing the run the fractions are measured by staining. The dye most commonly employed for this purpose is amido black 10B. The paper strip is dried and developed in a dye bath containing a saturated solution of the dye in a mixture of methanol and glacial acetic acid (9 : 1

v/v). Staining is allowed for 10 min with constant shaking.

After the electrophoretogram has been stained, the excess of dye is removed (destaining) by dipping the stained paper in baths of methanol–glacial acetic acid (9 : 1 v/v) several times. This destaining procedure is a slow process and can be made more efficient and faster by opting for electrophoretic destaining. After destaining, the paper strip is dried and scanned in a densitometer, i.e. the strip is illuminated and moved along the light source, the transmittance showing the distribution of the separated compounds. On plotting the reciprocal of transmittance against the wavelength one or more maxima are observed, depending upon the number of components. The amount of each component can be estimated by measuring the area under each peak. The estimation of serum proteins can also be done by an elution method. The destained paper strip is cut transversely into small pieces 5 mm wide, one unstained small strip at the end of the paper providing the blank value. The elution is done in 1.0 mol L⁻¹ NaOH in 50% ethanol + 0.25% (0.25 g per 100 mL) ethylenediaminetetraacetic acid (EDTA). After elution is over, the optical density is measured using a colorimeter.

A more rapid separation of serum proteins can be achieved using polyacrylamide gel electrophoresis. However, paper electrophoresis is still of particular interest where small amounts of protein need to be isolated for further analysis or testing.

Introduction

Two-dimensional (2D) polyacrylamide gel electrophoresis is a classical technique for the separation of proteins. It first appeared in the mid-1970s but for a long time it only found limited applications. Recently it has enjoyed an impressive renaissance. The major reasons for this are the introduction of the immobilized pH gradient (IPG) strips and the development of analytical methods capable of identifying proteins present in very low quantities. 2D electrophoresis represents the core methodology of the new, technology-driven science **proteomics**. Proteomics finds a wide application, in both clinical diagnosis and in pharmaceutical research, for the detection of novel drug targets. **Figure 1** demonstrates the application of 2D electrophoresis for the detection of variable protein levels between diseased and healthy brain tissue. In a sample from the parietal lobe of the brain of a patient with Alzheimer's disease, a strong spot representing glial fibrillary acidic protein (GFAP), a marker for neuronal loss, is pres-

ent, whereas in the control sample, the corresponding spot is very weak.

The aim of proteomics is the high throughput analysis of the proteome (protein complement expressed by a genome) of various organisms or tissues. It consists of two steps: (1) the separation of protein mixtures by 2D electrophoresis, and (2) the identification of the separated proteins by analytical techniques, such as mass spectrometry and amino acid composition analysis. The process is facilitated by the use of highly sophisticated software for advanced image analysis and the high reproducibility of images in intra- and inter-laboratory studies. The 2D electrophoresis itself involves: (1) separation of the proteins on the basis of differences in their net charge, called isoelectric focusing (IEF), and (2) separation of the focused proteins on the basis of differences in their molecular masses. **Table 1** gives a summary of the most significant chronological events in the development of 2D electrophoresis. The state-of-the-art technology will be discussed without entering into extensive technical details that can be found in the literature provided.

First-Dimensional Separation (IEF)

Proteins carry positively and negatively charged side groups and are, therefore, amphoteric molecules. The

Figure 1 Partial 2D gel images showing human brain proteins from a control (A) and a patient with Alzheimer's disease (B). The proteins were separated on pH 3–10 nonlinear strips, followed by 9–16% SDS gels, stained with colloidal Coomassie blue. The spots representing glial fibrillary acidic protein (GFAP) in (B), a known marker of neuronal loss, are indicated.

protein charge depends on the pH value of the solution. IEF is an equilibrium process, during which, under the influence of a high voltage field the proteins move along a pH gradient, according to their net charge, to a position, where they have no net charge and consequently stop moving. This pH value is called the isoelectric point (pI). The resolving power of IEF is defined by the equation of Svensson:

$$\Delta pI = [D[d(pH)/dx] \cdot E - du/d(pH)]^{1/2}$$

where ΔpI = resolution capacity (pI difference required to resolve neighbouring spots), D = diffusion coefficient of the protein, E = field strength ($V\ cm^{-1}$), $d(pH)/dx$ pH gradient, $du/d(pH)$ mobility slope at pI.

According to this equation, the resolution capacity is influenced by the pore size of the gel, which affects the diffusion of the protein, the slope of the pH gradient and the voltage value.

An efficient and reproducible protein separation during IEF requires a stable pH gradient. There are two pH gradient systems in use. In the first one, the pH gradient is created by an excess of carrier ampholytes during the IEF run. Ampholytes are amphoteric compounds of low molecular mass with closely related pI values. Upon application of an electric field, the ampholyte molecules move and align themselves between the electrodes, forming a pH gradient, which increases from anode to cathode. This type of IEF is usually performed in tube acrylamide gels.

In the second pH gradient system, the pH gradient is immobilized and has been formed prior to IEF run. IPGs are formed by acrylamide derivatives, called immobilines, which are weak acids and bases with a buffering capacity. Immobilines are copolymerized in a polyacrylamide gel, such that a pH gradient is formed between basic and acidic molecules. When an electric field is applied, the pH gradient does not move. Only the charged molecules of the protein sample move and are focused according to their pIs into

narrow bands. This type of IEF is usually performed in strips of acrylamide gel fixed on a plastic sheet.

Carrier Ampholytes

The pH gradient formed by the carrier ampholytes during IEF can be affected by the amount of total protein loaded. Proteins when applied in large quantities, having themselves a buffering capacity, can affect the focusing position along the pH gradient and consequently the reproducibility. Therefore, factors such as protein quantity, temperature, voltage and chemicals can strongly affect performance. Only small quantities of protein (of the order of 0.1 mg) should be applied for IEF with the carrier ampholytes approach. The difficulties in controlling the various factors which affect reproducibility together with the difficulties of preparing and transferring the tube gels to the second dimensional separation, contribute to the reasons why carrier ampholyte-based IEF remained a scientific speciality of only a few laboratories. Nevertheless, these laboratories are able to control the conditions affecting reproducibility, so that IEF with carrier ampholytes is still used. This approach allows a very reliable protein quantification of complex mixtures. Because only a small amount of protein can be applied, 2D gels made following the carrier ampholyte approach are more suitable for analytical purposes. IEF based on carrier ampholytes can efficiently separate proteins with pIs within the pH range of 3–8. Proteins with higher pIs separate poorly due to cathodic drift during isofocusing. The cathodic drift is the result of a high electroosmotic flow, caused by the charged groups on the glass walls of the gel tubes.

IPG Strips

The increased application of two-dimensional gel electrophoresis today is to a large extent due to the introduction of IPG strips. The major advantage of using IPG strips is the ability to maintain high

Figure 2 Partial 2D gel images showing the high fidelity in the reproducibility of separation of bacterial (A, B) and mammalian (C, D) proteins. The proteins were separated as stated in the legend to Figure 1. (A, B). Separation of proteins of *Haemophilus influenzae* were 1.5 and 3.0 mg, respectively. (C, D) Separation of rat brain proteins, 1.5 and 2.0 mg, respectively.

reproducibility. The increase in reproducibility has allowed a high throughput analysis of proteomes and the application of larger sample quantities, a requirement for protein spot analysis. **Figure 2** provides examples of the reproducibility of separation of bacterial and mammalian proteins, following IEF on pH 3–10 nonlinear IPG strips. Although minor differences can be detected, the reproducibility concerning both the position and the intensity of the protein spots can be considered as satisfactory.

As mentioned earlier, immobilines are polymerized in a gradient, in a polyacrylamide gel, and the gel is then dried on a plastic sheet. Before the IEF run, the dry strips are rehydrated in a specific rehydration solution, containing a reducing agent, ampholites and high concentrations of urea and a zwitterionic or

nonionic detergent (usually CHAPS). Rehydration can also be performed in a solution containing the protein sample to be analysed (see sample application). Large numbers of strips can be rehydrated at a time and this represents an advantage of the method regarding high throughput analysis and performance. Today, IPG dry strips are commercially available from Amersham Pharmacia Biotechnology in two lengths—11 and 18 cm and in three pH ranges—3–10, 4–7 and 6–11. The pH 3–10 strips are available in a linear and non-linear (sigmoidal) form. The latter allow a more efficient focusing of proteins with pI values between 4.5 and 7. A large percentage of proteins from various organisms have pI values within this range. The dry strips can be kept frozen at -20°C for a long time (the expiration date is indicated on the packaging).

The use of narrow pH range strips (i.e. of 1 pH unit) provides a higher resolution and allows the detection of protein isoforms; this is an additional advantage of IEF using IPG strips. Strips of more narrow pH ranges are not currently commercially available and have to be prepared by the user. IPG strips can be made in any biochemical laboratory using a gradient marker and Immoblines of various pK values which can be purchased. Recipes for the preparation of IPG strips can be found in handbooks, for example in *Electrophoresis in Practice* (see Further Reading). On the narrow pH range the spots appear stretched compared to the wide range strips. **Figure 3** shows an example of a protein which appears as one spot following IEF after focusing on a pH 3–10 strip and as five spots after IEF on a pH 4–7 strip. IEF on strips of an even narrower pH range would result in the detection of additional spots resulting from further isoforms of the protein. Following IEF, the IPG strips can be either immediately used for the second dimensional separation or stored frozen at -20°C for long periods (for example, in petri dishes sealed with parafilm). Strips stored for 4 months have been used at -20°C without any

effect on the spot resolution. Longer storage times of up to 1 year have been reported.

Sample Preparation

Careful sample preparation is a prerequisite of a successful analysis. Most proteins are soluble and are easily recovered in the sample preparation solution, which includes urea, CHAPS, a reductant and, optionally, protease inhibitors. Recovery of the proteins that are insoluble in this solution is often a problem. A centrifugation step is necessary for removal of nondissolved material. The addition of thiourea and of a noncharged reducing agent, such as tributyl phosphine, to the sample buffer increases protein solubility during IEF. It would appear that hydrophobic interactions between proteins and the acrylamide gel of the IPG strips are responsible for protein losses during IEF. Nucleic acids present in the sample can also seriously affect spot resolution. Enzymatic digestion with an endonuclease prior to sample application is usually recommended.

Sample Application

The protein application mode can affect the amount of protein entering the IPG strip during IEF. There are several ways of applying the sample. In the system supplied by Amersham Pharmacia Biotechnology (Multiphor II), the sample is usually loaded into application cups (also supplied by Amersham Pharmacia Biotechnology). Up to 150 μL can be applied in one cup. The cups are fixed in special 'cup accommodating bridges' which are placed near the basic or acidic end of the strip. It seems that sample application at the basic end of the strip is more advantageous compared to the application at the acidic end. We have, however, found that simultaneous sample application at both the basic and the acidic ends of the strip can result in the detection of more and stronger protein spots compared to sample application at only one end. It also allows the simultaneous application of sample volumes larger than 150 μL . From a technical point of view, sample application using the cups is the most difficult operation to perform. The cups should touch the polyacrylamide gel on the strip, otherwise the sample will leak; they should also not damage the gel at the contact point, otherwise the proteins will not enter the strip.

An alternative method of sample application is the rehydration of the strip in a solution containing the protein sample. This approach is convenient to perform and theoretically it should result in the detection of all proteins present in the sample. However, more comparative studies are required to prove that this approach is more efficient than the loading of sample

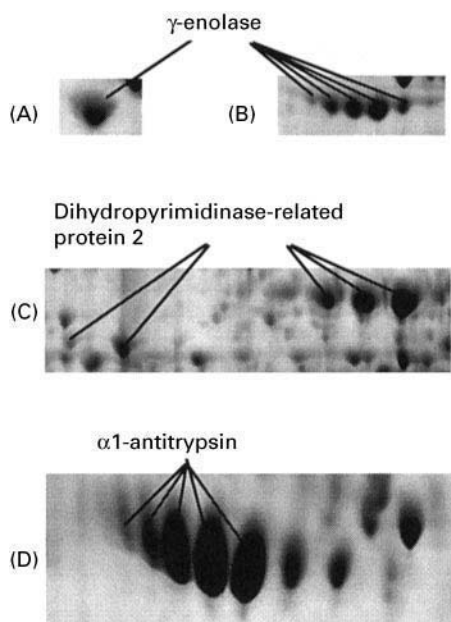

Figure 3 Partial 2D gel images showing examples of proteins represented by multiple spots. (A, B) γ -enolase from human brain. The protein is represented by one spot when IEF was performed on pH 3–10 nonlinear IPG strips (A), and by five spots when IEF was performed on pH 4–7 strips (B). (C) Dihydropyrimidinase-related protein 2 from human brain shows a high heterogeneity, represented by five spots, localized into two regions on the gel. (D) α 1-antitrypsin from human cerebrospinal fluid is represented by many spots, most likely denoting different glycoforms of the protein.

into cups. Amersham Pharmacia Biotechnology has recently introduced a new IEF apparatus (IPGphor) in which sample application and IEF can be performed. The strips are placed in special ceramic strip holders and rehydrated for the desired time in a solution containing the protein sample. Each strip holder holds a single IPG strip throughout rehydration and IEF. IEF starts automatically after rehydration according to the conditions programmed. Whether the performance of IEF will be improved with the use of this instrument is not clear at present.

The quantity of protein to be applied on the strip naturally depends on the goal of the analysis. If the identification of protein spots is intended, the amount loaded should be in the order of 1 mg or higher, depending on the number of proteins in the mixture. A 1D gel analysis of the sample prior to 2D electrophoresis may provide helpful information as to defining the right protein quantity. If large amounts of protein are applied, a percentage of the proteins may not enter the strip. Presently, this constitutes a drawback of the IPG strip approach. Because certain proteins in the sample (mainly major components) only partially enter the strip, this can result in an unreliable quantification of a particular protein in a given mixture. While the application of 15 mg or more of protein sample has been reported, we consider that 2–4 mg is the limit for a productive separation, using the strips that are presently available.

IEF using IPG strips can separate basic proteins efficiently with pIs up to about 12. The introduction of low concentrations of isopropanol in the rehydration buffer improves focusing of basic proteins. Hydrophobic proteins probably precipitate at the point of application and efficient separation has not yet been reported. Hydrophobic proteins can be analysed in a different 2D electrophoresis system, which uses the interaction of the proteins with a cationic detergent in the first dimension rather than pI. The second dimension is, as described below, dependent on the molecular mass. The separated proteins form approximately a diagonal line. Relatively, only a small number of proteins can be successfully separated using this approach.

Second-Dimensional Separation (Sodium Dodecyl Sulfate-Polyacrylamide Gel Electrophoresis, SDS-PAGE)

Following IEF, the proteins are separated according to their molecular masses. During this nonequilibrium

step, the proteins are negatively charged by addition of the anionic detergent SDS. Upon application of an electric field, the charged proteins move along a porous polyacrylamide gel and are separated according to their size. A reducing agent is also included to disrupt disulfide bonds. In comparison with IEF, SDS-PAGE is relatively easy to control. The terms ISO-DALT and IPG-DALT are often used to mean 2D gel electrophoresis employing IEF with carrier ampholytes or IPG strips, respectively.

Horizontal or more usually vertical slab gels, running in a discontinuous buffer system are employed. A high throughput analysis is facilitated by the use of tanks accommodating 6–20 gels running in parallel. An efficient separation of thousands of proteins present in complex mixtures, can only be performed on gels of a large format (18 × 20 or 25 × 25 cm). Either gradient gels or gels of a constant acrylamide concentration can be used. Because of the complexity of the

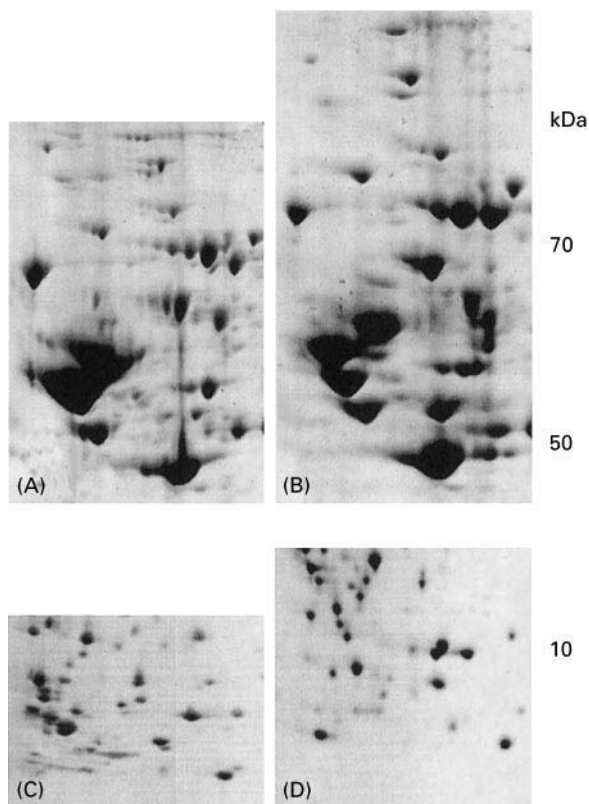

Figure 4 Partial 2D gel images showing an improved spot resolution by using different acrylamide concentrations. Separation of rat brain proteins on a 9–16% SDS gel (A) and on a 7.5–16% SDS gel (B). Separation of low molecular mass soluble proteins from *H. influenzae* on 9–16% SDS gel (C) and on a 10% SDS Tricine gel (D). (B, D) The gel parts comprising the corresponding proteins shown in A and B, respectively, are longer on account of the different acrylamide concentrations.

technology and the large diversity of the samples to be analysed, and in order for the data to be useful to a broad research community, 2D PAGE has been to a large extent standardized. In the second dimension, for example, we usually use 9–16% linear gradient gels. This gel system represents a good compromise, as it separates proteins between 5 and 200 kDa. However, efficient separation is limited to a range of approximately 15–40 kDa. Outside this range, in particular above 50 and below 10 kDa, the separation is often suboptimal. For more efficient separation, gels of a different acrylamide concentration should be tried. **Figure 4** gives examples of the improved separation of high molecular mass brain proteins using gels of lower acrylamide concentration and of low molecular mass proteins from *Haemophilus influenzae*, using gels with Tricine as the trailing ion instead of Tris.

For spot visualization, the gels can be stained with either silver or Coomassie blue (usually colloidal Coomassie blue), depending on the quantity of pro-

tein sample applied and the aim of analysis. Silver stain may be preferentially used for gel comparison studies, whereas staining with Coomassie is preferred when the spots are intended for protein identification. Colloidal Coomassie blue has the advantage that the stain is sensitive enough and the gels can be easily destained with water. The simultaneous staining of many gels in one tank substantially increases the throughput. Apart from silver and Coomassie blue, several other protein detection methods exist, such as staining with various metals, labelling with fluorescent agents or detection of radiolabelled compounds, after gel drying and exposure, for example to a film.

Proteome Analysis

An essential step of proteomics is the identification and mapping of the proteins separated by 2D electrophoresis. From a mammalian organism, comprising approximately 100 000 possible gene products,

Figure 5 Partial 2D gel images showing soluble proteins of (A) *H. influenzae*, (B) *E. coli* and (C) *B. subtilis*. The proteins were separated as stated in the legend to Figure 1. Note the similarity in the distribution of the major proteins in the three bacterial organisms.

approximately 1000–2000 protein spots can be visualized on one 2D-gel, using Coomassie blue. Higher numbers can be detected, following staining with silver or after radiolabelling. Approximately one-half of the visible spots are available in sufficient quantities to be analysed for identification. **Figure 5** shows the analysis by 2D electrophoresis of the proteomes of three bacteria, *H. influenzae*, *Escherichia coli* and *Bacillus subtilis*. The genomes of the three microorganisms have been completely sequenced, so that theoretically all expressed proteins can be mapped. This has however not yet been accomplished. The largest 2D proteome maps, such as that of *H. influenzae* prepared at F. Hoffmann-La Roche, Basel, include approximately 500 mapped proteins. Many of the unidentified proteins are not expressed in sufficient amounts to be visualized.

For the mapping of proteomes of the various organisms, protein enrichment steps need to be introduced before analysis. We have used several chromatographic steps, such as heparin chromatography, hydrophobic interaction chromatography, chromatofocusing, hydroxyapatite chromatography and several other approaches, to enrich the low-abundance gene products of *H. influenzae* and *E. coli*.

Additional enrichment steps are required for an efficient mapping of proteins present at low abundance, such as cytokines or transcription factors. **Figure 6** shows an example of protein enrichment by hydrophobic interaction chromatography. One protein (enolase), represented by a strong spot in the 2D map of the total protein extract, is highly enriched after chromatography. Another example of protein enrichment, this time using heparin chromatography is shown in **Figure 7**. In two fractions collected from the column, proteins which are not visible in the 2D gel image of the total extract can also be detected.

On a 2D map, proteins are often represented by more than one spot. **Figure 3C** shows an example of a brain protein represented by five spots, in two locations, with different *pI* and *M_r* values. Presently, we do not know the reasons and the biological significance for most of these cases of observed heterogeneity. It may be the consequence of post-translational modifications, such as deamidation, phosphorylation or glycosylation, which result in the alteration of the *pI* of the molecule and its focusing position. Another reason may be the carbamylation of the protein upon contact of the sample with urea. In **Figure 3D** an

example of protein heterogeneity, most likely due to glycosylation, is presented.

Following 2D electrophoresis, proteins can be identified by mass spectrometric analysis of the peptides resulting from the in-gel digestion with a specific

protease, such as trypsin. In another approach, the proteins can be electrotransferred onto membranes and identified by immunoreaction with specific antibodies, by N-terminal sequencing or amino acid composition analysis. For those proteins for which the

Table 2 Steps in the preparation of 2D electrophoresis

IPG strip rehydration and sample preparation

Protein extraction, centrifugation, recovery in sample solution

Sample application

Application in cups at either or at both ends of the strip or strip rehydration in a solution containing the protein sample

First dimensional separation (isoelectric focusing)

Start at 200 V and increase gradually to 5000 V; keep 5000 V for 6–48 h, depending on sample, quantity and strip range; narrow pH range strips require longer focusing times

Reduction and alkylation of proteins on IPG strip

Equilibration of strip with reducing and alkylating agents or freeze until use

Second dimensional separation (SDS-PAGE)

Preparation of gel of the desired acrylamide concentration; gels should carry a label to identify them afterwards; establishment of contact between strip and gel with agarose solution; run at 40 mA/gel

Protein fixing and staining or blotting

Fixation of proteins within the gel and staining with silver or Coomassie blue or drying of the gel and exposure to a film or phosphorimager for detection of radiolabelled proteins or electrotransfer of proteins to membranes for immunoblot, MS or amino acid analysis

Gel scanning

Storage of image in a database

Gel comparison

Gel comparison and protein quantification using specific software; comparison with database master gels via the WorldWideWeb

Identification of proteins

Identification of protein spots from gels by mass spectrometry or from membranes by N-terminal sequencing, amino acid composition analysis, MS or immunoblots

genomic sequence is in a database, the most efficient identification method presently available is matrix-associated laser desorption ionization mass spectrometry (MALDI-MS) with which about 500 spots can be analysed daily by one person. The method tolerates small amounts of salt in the sample, so that no time-consuming desalting steps are required after digestion. Several approaches using a combination of protein digestion on membranes and MS have also been reported. **Table 2** summarizes the essential steps of 2D electrophoresis and protein analysis.

Future Developments

2D electrophoresis is still in a developmental stage. Several technical improvements, mainly concerning further simplification of the technology and possible automation, an increase in reproducibility and sensitivity, and expansion of the pH detection spectrum, have to be achieved in order for the method to become routine in any biochemical laboratory. Gel grinding techniques, together with sophisticated software using the mass spectroscopic data, may be developed to produce a gel image without previous staining of the gel. Such a development could be decisive as to whether the technology will reach its major goal, i.e. the investigation of biological problems by a faithful comparison of protein expression levels. The completion of the sequencing of more genomes together with improvements in the analytical techniques will also

lead to a more widespread application of the technology.

Introduction

The evolution of tools utilized in biology and medicine, together with the exponential progress accomplished recently in the area of bioinformation, enables analysis of whole organism constituents. Such analyses are best exemplified by complete genomic sequences of different microorganisms, and by the recent development in techniques permitting dissection of the whole protein repertoire of an individual, namely its proteome. Furthermore, the dramatic growth in the number of genome projects as

well as the speed with which genome sequences are determined has generated huge amounts of information. This progress has boosted techniques, notably two-dimension polyacrylamide gel electrophoresis (2D-PAGE), enabling the analysis of a proteome consisting of all the proteins expressed by a genome. Such analyses give information on the effector molecule itself, namely the protein, and take into account highly sophisticated mechanisms regulating gene expression. 2D-PAGE is the most powerful tool to separate a multitude of polypeptides that are contained in a single biological sample. Various procedures have been described to separate proteins according to biophysical parameters. In 1975, O'Farrell, Klose and Scheele described optimized 2D procedures in which proteins were denatured and separated by electrophoresis on polyacrylamide gel. The first gel dimension comprised a separation according to the protein charge by isoelectric focusing,

and the second gel dimension separated proteins according to their sizes. Thus, peptides are separated from one another according to two independent biochemical properties. 2D-PAGE was shown to be particularly valuable in the study, as well as in the identification of thousands of cellular or secreted proteins, including many of those present in human plasma/serum (Figure 1).

During the past few years, tremendous progress has been made in the field of 2D-PAGE. The 2D technique has been simplified, and, more importantly, made reproducible. Commercially manufactured im-

mobilized pH gradients (IPGs), with both acidic and basic high resolution power and precast sodium dodecyl sulfate (SDS) PAGE gels are now available. In addition, progress in protein solubilization and in the development of systems allowing high loading capacities has been made.

More than 20 years after its birth, 2D-PAGE is now a major technique in protein sciences. Over the past few years there has been an exponential increase in the creation and expansion of protein databases such as the SWISS-2DPAGE, the HEART-2DPAGE and the HSC-2DPAGE. Furthermore, tools have been developed to

Figure 1 The normal human plasma 2D map. Polypeptides (0.3 μ L of plasma) were separated by pH 3.5–10 carrier ampholyte gradient, followed by gradient 9–16% T polyacrylamide gel electrophoresis in the presence of sodium dodecyl sulfate (SDS). compare 2D gels images across the Internet. Most importantly, methods for the analysis of 2D gels are continually improving. The high sensitivity and throughput of these techniques now enable the characterization of hundreds of proteins from a whole cell, tissue or body fluid. Proteins can be identified according to primary parameters such as their isoelectric points, apparent molecular mass, real mass and protein N- or C-terminal sequence tag, but also according to secondary attributes such as peptide mass fingerprint, peptide fragmentation data or amino acid composition. Interfacing and integrating databases from 2D gels such as SWISS-2DPAGE, SWISS-PROT, GenBank, EMBL nucleotide sequence database, dbest, GSBD and the NLM's MEDLINE bibliographical reference database provide researchers with invaluable tools to study both genome and proteome. The continuing progress accomplished in both proteome research and bio-information will contribute to the implement of the *Cyber-Encyclopedia of the Proteome*, as suggested by R.D. Appel. This development increases the need for simple protocols to run reproducible 2D gels and is an important step for investigators involved in proteomics. Several well-written protocols and reviews are accessible in the literature or through the World Wide Web (<http://expasy.hcuge.ch/ch2d/technical-info.html>; <http://www.abdn.ac.uk/~mmb023/2dhome.htm>). We will review here some of the important features that must be evaluated in order to implement a new 2D-gel laboratory.

Sample Preparation and Protein Solubilization

2D-PAGE is an ideal separation tool. Nevertheless, sample preparation and protein solubilization are still a key step that is frequently ignored. In addition, there is no universal and ideal sample buffer for 2D-PAGE. The goal of sample preparation is to maximize solubilization and disaggregation of the tissues while preventing protein degradation. For these reasons, and because samples have various characteristics, protocols have to be adapted according to the origin of the samples. Sample preparation is quite easy with soluble proteins such as those of plasma or cerebrospinal fluid, but presents major difficulties in the presence of membrane or nuclear proteins. Tissue samples are usually mechanically disrupted (ultrasonication, rapid agitation in the presence of glass or zirconium microspheres), washed in a low salt buffer and then chemically (lysis buffer) solubilized. Constituents such as nucleic acids, lipids or salts can interfere with both solubilization and with the electrophoretic properties of the proteins. Before loading, nonsolubilized material must be eliminated by high

speed centrifugation. To break down interpolypeptide disulfide bonds and to maintain reducing conditions, components such as dithiothreitol, dithioerythritol or β -mercaptoethanol are used. The solubility problem can be alleviated to a large extent by the proper use of a combination of chaotropes and detergents in combination. Urea is a common constituent of protein sample preparations, and in its presence care must be taken to avoid heating above 32°C, which causes carbamylation of peptides. Impressive improvements in protein solubilization have been obtained with a denaturing solution containing urea, thiourea and detergents (both nonionic and zwitterionic). The ideal conditions would combine the highest chaotropic power (i.e. 2 mol L⁻¹ thiourea and 7–8 mol L⁻¹ urea) with a detergent cocktail (3-[(3-cholamidopropyl)dimethylammonio]-1-propane sulfonate, Triton X-100).

The main problem encountered with thiourea is the strong inhibition of acrylamide polymerization. Another problem complicating protein separation by 2D-PAGE is that, at high concentrations, many proteins are prone to precipitation, resulting in poor resolution after isoelectric focusing. In order to load large amounts of proteins, investigators have overcome the problem by using 'in gel' application of the samples, avoiding the use of sample cups and eliminating precipitation at the same application site.

Isoelectric Focusing

In 1964, synthetic carrier ampholytes (aliphatic oligoamino and oligocarboxylic acids) were synthesized allowing separation of peptides according to their charges. For 2D-PAGE, carrier ampholyte isoelectric focusing is usually performed in an ampholyte–polyacrylamide matrix that is polymerized in a glass tube. After sample loading, polypeptides are concentrated into narrow bands within a continuous pH gradient in the polyacrylamide gel matrix. Proteins migrate in an electric field until they arrive at a position in which they have no net charge, i.e. their isoelectric point (pI). Isoelectric focusing is useful because: (i) no diffusion of proteins occurs because of the focusing effect; (ii) it offers a resolution allowing the separation of microheterogeneous populations of proteins; and (iii) the pI of the protein can be estimated. In the past, pH gradients were generated by carrier ampholytes or amphoteric buffer moving freely within an acrylamide matrix.

Practically, many factors can affect measurement of the apparent pI of the proteins during isoelectric focusing with carrier ampholytes: (i) since the proteins have their own inherent charges, they can act as ampholytes themselves and affect pH during focus-

ing; (ii) the carrier ampholytes have a higher mobility than the proteins; (iii) some proteins may never reach steady state due to polyacrylamide gel matrix restriction; (iv) ampholyte-protein interactions may alter the observed pI of the proteins. Temperature, time, voltage and salt concentration are other parameters that may dramatically influence the determination of the pI . Finally, the basic proteins are not detected without using nonequilibrium pH gradient electrophoresis. Nowadays, many of these problems have been resolved by the development of isoelectric focusing with an IPG. The pH gradient is created by copolymerization of acrylamide/ N,N' -methylenebisacrylamide with acrylamido derivatives, containing either carboxyl or tertiary amino groups as buffers and sulfate groups (acidic) or quaternary ammonium (basic) as strong titrants (Immobilines). This method is a true equilibrium method, which significantly improves the feasibility of the 2D-PAGE.

Recently, highly reproducible, commercially available, wide-range as well as narrow-range IPGs have been produced. The latter gradients allow a pH scale that enables comparison of several 2D gel maps generated with many IPGs in the first dimension and with various biological samples. IPGs also offer the possibility of determining pI without major differences from the calculated pI values, unless there are significant post-translational protein modifications. Nowadays, with the improvements of IPG production, it is possible to detect proteins with pI s up to pH 12 in a single IPG gel with highly reproducible protein patterns.

Finally, as mentioned in the previous section, entire IPG gels can be used for sample application, with the protein entering the gels during their rehydration. This approach is useful because it eliminates precipitation at the sample application site, it improves the resolution over the entire pH range of the gels, and it allows precise control of protein amounts and sample volumes loaded on to the IPG gels. Up to 5 mg of proteins can be loaded on wide IPG gels and up to 15 mg on narrow pH range gels. Contrarily to isoelectric focusing with carrier ampholytes, electroendosmosis (transport of water towards the cathode at low pH values or towards the anode at high pH values) is generally not a problem with IPGs. Currently, isoelectric focusing using carrier ampholytes still has a place in a 2D laboratory, because the resolution of particular proteins is sometimes better.

From the First to the Second Dimension

Transfer of the first-dimension spaghetti-like gels after isoelectric focusing in the presence of am-

pholytes used to be a manipulation challenge for beginners in the field of 2D-PAGE. Extrusion of the gels from the glass tubes was difficult, and the gels frequently broke into several pieces. With the use of IPG strips, which are deposited on a plastic backing material, the transfer is easy. Practically, after the first dimension run, the strips are equilibrated in buffers containing SDS in order to maintain proteins in solution and to reduce $-S-S-$ bonds. Subsequently, strips are placed over SDS gels that may or may not contain a stacking gel.

SDS-PAGE

In the second dimension, polypeptides are separated according to their size in a gel matrix. Practically, after electric focusing in reducing conditions, proteins are separated into their polypeptide components. The latter are mixed with SDS-containing buffers. SDS binds to polypeptides at a constant mass ratio (1.4 g SDS per gram of protein). As a consequence, polypeptides organize as rod-like molecules, with a diameter of 1.8 nm, and their lengths depend on their molecular weight. The bound SDS molecules contribute to a strong negative charge, which effectively swamps the intrinsic charge of the polypeptides. Thus, in general the SDS-polypeptide complexes have the same mass/charge ratio and, in a sieving polyacrylamide matrix, they will migrate according to their molecular weight. Glycoproteins and lipoproteins can migrate abnormally as they are not easily saturated with SDS.

The gel matrix is most frequently composed of polyacrylamide generated by polymerization of acrylamide monomers into long chains that are cross-linked. Usually, cross-linkers are bifunctional components such as N,N' -methylenebisacrylamide (bis) or diacrylpiperazine. Polymerization of acrylamide is initiated either by the use of ammonium persulfate or riboflavin, and is accelerated by the use of N,N,N',N' -tetramethylethylenediamine (TEMED). Oxygen inhibits polymerization, and thus gel mixtures are usually degassed. The composition of a polyacrylamide gel is defined by two parameters: % T and % C . The % T (w/v) is the total concentration of the monomer (acrylamide plus cross-linker), whereas % C corresponds to the ratio (w/w) of the cross-linker to the acrylamide. The pore size of the polymerized acrylamide will depend on these two parameters, but since pore formation is random, pore sizes will never be totally uniform. The choice of the mean pore size will depend on the molecular weight of the proteins to be studied. The second-dimension SDS-PAGE can be performed with home-made vertical or horizontal systems, using linear or gradient polyacrylamide

(9–16%) gels. Commercially manufactured gels are also available. The advantages of the latter reside in their reproducibility and safety (polymerized acrylamide being clearly less neurotoxic as compared with monomeric acrylamide). The sensitivity as well as the resolution power of the protein detection must be kept in mind before choosing optimal conditions for SDS-PAGE. Gels polymerized with the photoinitiator system, composed of methylene blue, toluene sulfinate and diphenyliodonium chloride, lead to low resolution power after silver staining. Resolution can be restored if methylene blue is replaced by riboflavin. Gels polymerized with the riboflavin/sulfinate/iodonium system yield better results upon *N*-terminal microsequencing after blotting than gels polymerized with the standard TEMED/ammonium persulfate system.

Protein Visualization

Several methods have been described to detect protein spots after 2D-PAGE. These methods use reactants

such as Coomassie Brilliant Blue R-250, Amido Black, Ponceau S, Fast Green, negative staining, silver staining, fluorescein and radioisotopes. The two most popular approaches are Coomassie Brilliant Blue R-250 and silver staining. A good stoichiometric relationship has been documented between protein abundance and integrated optical density of protein spots for Coomassie Brilliant Blue R-250. The silver staining methods are more sensitive than those using Coomassie Blue and can detect as little as 1–4 ng of proteins. Several methods of silver staining of proteins have been described, with the most rapid ones being usually less sensitive and less reproducible than the more time-consuming ones. Among the latter methods, those using silver–diamine complex give the most uniform sensitivity. However, they require special home-made gels and cannot be applied to several electrophoretic systems. For these reasons, protocols based on silver nitrate are of more general use and are favoured. A variety of systems using different metal cations (K^+ , Cu^{2+} , Zn^{2+}) has been

Figure 2 Microheterogeneity of proteins. 2D gel of a cryoprecipitate containing fibrinogen (cryofibrinogen). developed to stain SDS-PAGE separated proteins without the need for fixative, organic dye or chemical modifier. SDS proteins stain negatively upon gel treatment with solutions of heavy metal salts. The zinc imidazolate reverse-staining method offers the advantage of combining good sensitivity, rapidity and reversible interaction. Furthermore, the zinc imidazolate reverse-staining method can be used in situations where Coomassie Brilliant Blue R-250 or silver staining is inappropriate or fail to produce detection of the polypeptides of interest.

Protein Microheterogeneity

Polypeptides separated by 2D-PAGE rarely appear as single spots, and most are resolved as multiple spots characterized by charge and size microheterogeneities (Figure 2).

Microheterogeneity is due to several factors that frequently occur together. The first cause of microheterogeneity is genetic polymorphism where heterozygote individuals express both forms of the gene (Figure 3); the second is related to protein co- and post-translational modifications. These modifications are multiple and have all the potential of modifying a protein's charge, hydrophobicity, conformation and/or stability. Furthermore, the 'one gene one polypeptide' paradigm is challenged by the alternative splicing of many genes responsible for synthesizing several proteins from a single gene. An important feature of 2D gel analysis is that various protein isoforms generated by co- and/or post-translational modifications can be separated by isoelectric focusing and/or by SDS-PAGE. Among the modifications which lead to a charge-dependent change to a protein, acylation, alkylation, carboxymethylation, phosphorylation, sulfation, carboxylation, sialylation and proteolytic processing are involved. Finally, glycosylation of proteins may lead to both charge and size modifications, and microheterogeneity of a protein may reflect the presence of several glycoforms.

Protein Identification

Several approaches have been used to identify proteins after 2D-PAGE. Co-migration with purified known proteins and Western blotting were employed by the pioneers of the 2D field. The use of specific antibodies and the recent developments of antigen-antibody interactions with enhanced chemiluminescence allow detection and identification of traces of proteins. However, monoclonal antibodies may not detect denatured polypeptides. Nowadays, proteins are identified by microsequencing, amino

Note the microheterogeneity of haptoglobin β chain spots, which present both charge and size heterogeneities.

acid analysis, peptide mass fingerprinting and/or mass spectrometry. The development of automated, high throughput technologies for the rapid identification of proteins is in progress. Automation already exists in several stages of the protein identification process. This includes automated acquisition of matrix-assisted laser desorption ionization-time-of-flight mass spectra and peptide mass fingerprinting. Bioinformation allows identification of proteins by mixing several databases (a classified index can be found at the following address: <http://expasy.hcuge.ch/alinks.html#Proteins>).

Data Management

Many investigators have analysed their 2D gels by holding two, sometimes three gels together towards a light source, and tried to identify differences between them (Figure 4). However, analysis of a multitude of 2D gels, with its bulk of information is greatly

Figure 4 Analysis of 2D gels. 2D gels of human platelets from a single blood donor (pH 3.5–10 carrier ampholyte gradient). (A) Platelets stored with leukocytes, 1 day after collection; (B) platelets stored in the presence of leukocytes, 7 days after collection; (C) platelets stored in the absence of leukocytes, 7 days after collection. facilitated by the use of computer-based data processing. The improvements in image acquisition and image analysis allow clear spot detection, background subtraction, spot matching and database construction. Furthermore, interpretation of 2D-PAGE images is facilitated by statistical methods, artificial intelligence and machine-learning programs. Ascendant hierarchical classification sorts the image into meaningful groups. The use of correspondence analysis and ascendant hierarchical clustering allows identification of new, potentially important proteins. Many database of 2D gel master images are accessible through the World Wide Web (Internet sites can be found at the following addresses: <http://www.expasy.ch/ch2d/2d-index.html> or <http://www.lmmb.ncifcrf.gov/ABRF97/abrf3.html>). It is also possible to compare 2D gels from various laboratories, or 2D gels with masters, on the World Wide Web by using the flicker created by P.F. Lemkin (accessible at <http://www-lecb.ncifcrf.gov/flicker/>).

Protein Functions

After 2D-PAGE analysis of cells, thousands of spots are observed. Such an observation is frequently impressive, but not very useful. Identification of the polypeptide sequence corresponding to a spot is already undergoing major progress. However, understanding the protein's function(s) remains the final goal of any analysis. It is also relevant to study the expression level, the phosphorylation state, the sub-cellular location, the association with other proteins and the rate of synthesis or degradation of the

proteins of interest. Combination of all this information will make possible the study of a functional proteome.

Concluding Remarks

Amino acids are like letters. Amino acids make proteins; letters make words. Proteins are like words. Some are known, others are unknown. Proteome databases are like dictionaries; they contain a lot of information and are very useful. Organization of the words makes the texts; organization and regulation of protein production make the cells. 2D-PAGE is a major proteomics tool. The technique should be applied to resolve specific biological problems. It should not be used for random investigations.

Introduction

The process of generating analytical data involves some combination of planning, sampling, sample preparation, quantification, data review and reporting. Initially, each step in the method required comparable effort. Sample preparation, generally involving some form of extraction followed by analyte enrichment, has in the past been a laborious process, with only a few tools available. Likewise, quantification usually consisted of a 'wet' chemistry process such as titration or precipitation. Before the development of personal computers, the planning, sampling, data review and reporting steps also required considerable effort. Since each step presented formidable challenges to the analytical scientist, the relative importance of each step remained about the same.

Modern techniques, particularly chromatography, have changed the situation. The rapid and successful development of gas and liquid chromatography dramatically reduced quantification steps from hours or days to a matter of minutes, often with better accuracy and precision. The other steps in the method,

especially sample preparation, were regarded as of secondary importance, serving only to support the ultimate (i.e. chromatographic) step in the method. Since most of the creative – and financial – resources flowed into chromatography development, research in the other areas slowed and sample preparation came to be viewed as the 'low tech' part of the method.

Chromatography is now considered a mature science, being an integral part of nearly every analytical laboratory. The slower pace of chromatographic research, coupled with outside pressures to improve the efficiency of the entire analytical method, has finally resulted in an increased interest in sample preparation. These efforts have produced a number of advances that improve efficiency, selectivity and time required. The discussion will provide an overview of some of the many sample preparation principles and techniques available, focusing on the analytical extraction part of the process. The goal is to provide the reader with a more balanced view of this important part of analytical methodology.

Principles of Extraction

Developing a successful extraction as part of an analytical method requires an understanding of the chemical and physical principles involved. Thus, we will begin this discussion of analytical extraction by focusing on the underlying principles that make the techniques work. Only with understanding and

appreciation of these principles can full advantage be taken of them.

Definition of Analytical Extraction

Extraction is the process of moving one or more compounds of interest (analytes) from their original location (usually referred to as the sample or matrix) to a physically separate location where further processing and analysis occur. The sample may be a solid, liquid or gas. The separate location is usually a fluid (an extracting solvent), but extractions into the gas phase and on to solid sorbents are also common. Finally, the word analytical implies that this process involves small amounts of analyte (as opposed to preparative extraction). Most analytical methods aim at complete extraction although situations frequently exist where good analytical results are possible with only partial extraction.

Thermodynamics and Kinetics

These two terms are often interchanged, when in fact they have very different chemical meanings. Thermodynamics is the study of energy, in this case the energy associated with the chemical process of extraction. Through this study of energy, we can determine if the process is favourable or unfavourable. That is, will this extraction give a good result or a bad one? Even if the process is favourable, it may not happen quickly because of kinetic factors. Kinetics is the study of the rate at which these processes occur.

It is important to realize that these two principles are completely independent of each other. Complete extraction is not necessarily a fast process and devel-

opment of a successful extraction method requires that consideration to be given to both aspects.

Like Dissolves Like

A compound will be soluble in, or mix with, another compound that is chemically like it. That is, the two compounds must be from the same, or similar, chemical families. This simple principle is an implied requirement in every analytical extraction. The concept of moving analytes from the matrix to some other location requires them to be transported using some medium in which they are soluble. Therefore, we must carefully consider how the like-dissolves-like concept can help to achieve the desired result: extracting the desired compounds and not extracting the undesired ones.

Figure 1 illustrates how simple changes in molecular structure can have a profound influence on solubility behaviour. This plot shows the solubility of three related amino acids in water. Amino acids are generally considered to be polar, so their solubility in the polar solvent, water, is generally high. As nonpolar functionality is added to the molecule, in the sequence from glycine to phenylalanine, the nonpolar character of the entire molecule increases (i.e. it becomes less like water). The result is a significant reduction in water solubility.

The same situation exists when considering the relative solubility of any compound in a series of solvents. A higher solubility will be observed when the solvent is most like the compound in question. The reader is referred to the Further Reading section for additional examples.

Figure 1 Solubility of amino acids in water as a function of structure.

Temperature Effects

Temperature has an effect on three important phenomena: solubility, vapour pressure and kinetics. While increasing temperature generally increases the magnitude of each effect, there are some aspects of this principle that are particularly relevant to analytical extractions.

Effect of temperature on solubility In most cases involving organic analytes, increasing the temperature of a liquid results in increased analyte solubility. **Figure 2** illustrates that for the same three amino acids as shown in **Figure 1** a temperature increase from 0 to 75°C results in a three- to fourfold increase in solubility. Even marginally soluble compounds show a dramatic improvement from this simple change in conditions. Indeed, as will be seen later, this principle is used in most extraction procedures.

Effect of temperature on vapour pressure Increasing the temperature of a liquid will result in an increase in vapour pressure. Boiling occurs when the vapour pressure above the liquid equals the applied (usually atmospheric) pressure.

Figure 3 shows calculated vapour pressures for several common solvents. Note that the vapour pressure is relatively large at temperatures as much as 20°C below the boiling point of the solvent. Simple evaporation in a stream of nitrogen at room temperature uses this fact to evaporate a solvent rapidly without boiling. If the applied pressure is raised, the boiling point is also raised, so that the solvent can be maintained in its liquid state at higher temperatures. Press-

urized fluid extraction uses this phenomenon to advantage. Similarly, lowering the applied pressure, as in a rotary evaporator, reduces the boiling point, allowing faster evaporation at lower temperatures. Finally, at any given temperature, the relative vapour pressure of each compound above the liquid phase provides an estimate of the relative evaporation rates of the liquids. Such knowledge is essential when performing critical steps such as solvent evaporation or solvent exchange.

Effect of temperature on kinetics All chemical processes are affected by the temperature at which the process is occurring, although the exact change in reaction rate with temperature is unique for any process. However, many reaction rates will approximately double for each 10°C increase in temperature, and this rule of thumb can be a helpful guide in understanding the effects of temperature changes. These changes can be either positive or negative, depending on whether the temperature change is increasing or decreasing. For example, storing samples and solutions at low temperatures slows down evaporation and degradation. These processes are about four times slower if the solution is stored at 4°C compared to room temperature.

Effect of pH

The pH of an aqueous sample will influence the success or failure of an extraction for acidic and basic analytes. Acids and bases involve an equilibrium between two forms, one neutral and one ionic. Each form has significantly different chemical and physical properties, as noted in **Table 1**.

Figure 2 Solubility of amino acids in water as a function of temperature.

Figure 3 Vapour pressure of common solvents as a function of temperature. (Calculated from data in *Handbook of Chemistry and Physics* (1971).)

Extraction of organic acids from water is only practical at pH values more than two units below the pK_a of the acid. Only at this pH is most of the compound in the neutral form and amenable to extraction with an organic solvent. Similarly, to keep a base, such as an aromatic amine, in the neutral (extractable) form, the pH of the solution must be adjusted to at least two units above the pK_b of the base. Readings with a pH meter are likely to be unstable and/or unreliable in the presence of organic solvents, and the equilibrium constant, K_a , is also

likely to change, often in an unpredictable way. Any required pH adjustments and measurements must, therefore, be made before the organic component is added.

Two-phase Distribution Equilibria

Definitions The process of extraction, by definition, requires that the analyte be transferred from the matrix to a different phase. When the extracting medium first contacts the matrix, the analytes will become distributed between the two phases in a well-defined ratio. Since the matrix is usually a liquid or solid, and the extracting medium can be a solid, liquid or fluid, this usually refers to liquid-liquid and liquid-solid distribution equilibria.

These distribution equilibria can be described by several important equations. First, the distribution ratio, D , for extracting from phase 1 into phase 2 is defined as:

$$D = \frac{C_2}{C_1}$$

where C is the stoichiometric concentration of the analyte in each of the phases. (Actually, D is related

Table 1 Properties of individual forms in acid-base equilibria

Neutral form		Ionic form	
HA + H ₂ O	\rightleftharpoons	A ⁻ + H ₃ O ⁺	
Acid		Conjugate base	
B + H ₂ O	\rightleftharpoons	BH ⁺ + OH ⁻	
Base		Conjugate acid	
More soluble in organic solvents		Less soluble in organic solvents	
Insoluble in water		Soluble in water	
More volatile		Nonvolatile	
Sour/bitter taste, bad odour		Little odour	

to the ratio of activities rather than concentration, but in dilute solution the difference is negligible.)

This ratio is a constant that depends on the analyte, the two phases, the composition of the phases (pH, ionic strength, etc.) and the temperature.

The fraction extracted, θ , in any one equilibration is defined as:

$$\theta = \frac{D\beta}{1 + D\beta}$$

where β is the phase ratio, the ratio of the volumes of the two phases ($= V_2/V_1$). The fraction remaining in the initial phase (V_1) is, of course $1 - \theta$.

The amount extracted depends on the physico-chemical interactions between the two phases and the analyte, and the volume of each phase. A change in these variables will cause a change in the extraction result.

Effect of analyte structure on D Actual values of D in Table 2 show how simple changes in molecular structure have a profound influence on the success of an extraction.

The addition of nonpolar functional groups (methyl- and chloro-) to benzene make the molecule more nonpolar, so that the new molecule favours the hexane phase (larger value for D). Conversely, adding polar groups (amine, hydroxy, carboxylic acid) makes the molecule more like the water phase (smaller D). It is important to keep these general principles in mind when developing an extraction method and understanding the results.

Multiple extractions When multiple extractions are performed on the same sample, the amount extracted into phase 2 and the amount remaining in phase 1 are calculated using the equations shown in Table 3.

In general, several extractions with the same total volume of extracting solvent will always produce better recovery than a single extraction with the same

Table 3 Equations used for multiple extractions

Extraction number	Fraction extracted into phase 2	Fraction remaining in phase 1
1	θ	$1 - \theta$
2	$\theta(1 - \theta)$	$(1 - \theta)^2$
3	$\theta(1 - \theta)^2$	$(1 - \theta)^3$
n	$\theta(1 - \theta)^{n-1}$	$(1 - \theta)^n$

volume of solvent, although it is seldom worth carrying out more than three extractions.

Effect of variations in D and β The effects of variations in D and β on extraction results are shown in Table 4. The total recovery after multiple extractions is calculated for various combinations of D and β . These calculations show the importance of all three variables: phase ratio, distribution ratio and number of extractions.

In summary, two-phase distribution equilibria are an important part of every analytical extraction, and the laboratory scientist must ensure that all critical variables are controlled in order to generate reliable results.

Other Principles

The preceding principles do not represent an exhaustive list. Certainly, there are other chemical principles that contribute to the extraction process, but play a more minor role. Some of these are discussed briefly below.

Time A longer extraction time will usually produce better recoveries, but this effect assumes that the

Table 2 Distribution ratios for extraction from water into hexane

Analyte	Added functional group	Functional group category	D (25°C)

analytes, reagents and solvents are nonvolatile, stable and do not react with each other. If these assumptions are not valid, longer extraction times may actually produce poorer recoveries.

Ionic strength The addition of ionic species to an aqueous solution results in a 'salting-out' effect. This procedure often enhances extraction of neutral organic analytes from water by increasing D .

Surface area Reducing the particle size of a solid matrix, thereby increasing contact areas between phases, can cause a dramatic increase in extraction rates.

Stirring/mixing Adequate stirring enhances the rate of procedures that are otherwise limited by diffusion processes.

Analytical Extraction Techniques

This discussion will focus on the most popular traditional techniques, and provide an introduction to some of the newer extraction technologies. In each case, the principles involved will be considered together with some practical operating tips.

Liquid-Liquid Extraction Techniques

Separatory funnel techniques There are few limitations on what size or type of liquid samples can be extracted, except that the two liquid phases must be immiscible and unreactive with each other. Separatory funnels are available to handle samples from as small as a few millilitres to several litres. Extraction times vary from 1 to 15 min, depending on the specific requirements of the method, but equilibration is usually fast in all but the most viscous liquids. As noted in the section on principles of extraction, multiple extractions with a smaller volume of extracting solvent are preferred over a single extraction with a larger volume. The primary disadvantages of separatory funnels are the labour necessary, the need to evaporate an often large volume of solvent and the formation of emulsions.

The following practical points should be considered:

- **Funnel size:** to allow adequate mixing, the flask size should be chosen so that at least 25% of the funnel volume is free space.
- **Venting:** regular venting is a required safety procedure, especially at the start of the extraction process.
- **Draining layers:** too much time should not be

wasted draining off one layer, except after the final equilibration.

- **Shaking:** the most important variable is the time spent shaking the two layers, not the intensity of the shaking. Because of this, automated shakers provide adequate extraction, even though the intensity of mixing may be quite low.

Continuous liquid-liquid extractors These systems are usually reserved for larger water samples and/or situations where a long extraction time is required. There are two basic design types, depending on whether the extracting solvent is more dense (Figure 4) or less dense (Figure 5) than water. In each design, the solvent in the flask is heated to boiling, causing solvent vapours to collect in the condenser. The condensed solvent then passes through the sample in the main chamber.

The principles are the same as for separatory funnel extractions. However, each drop of solvent represents a separate two-phase distribution system with a small phase ratio but high surface area and fast extraction kinetics. Since each drop represents an equilibration step, the extraction consists of thousands of multiple extractions. The result is generally a high analyte

Figure 4 Continuous liquid-liquid extractor for use with extracting solvents that are denser than water. (Reproduced from Burford and Hawthorne (1994) *Journal of Chromatography A* 65: 75-94, with permission of ACCTA, Inc.)

Figure 5 Continuous liquid-liquid extractor for use with extracting solvents that are less dense than water. (Reproduced with permission of ACCTA, Inc.)

recovery. The primary disadvantages are the set-up time, lengthy extraction time (6–24 h), and large quantities of solvent. The latter problem has been solved somewhat by integrated extraction systems that allow extraction, evaporation and concentration of solvent in one apparatus.

For continuous liquid-liquid extractors the following considerations are important:

- The extractor only works properly if the condensed solvent passes through the bulk of the sample, rather than along the sides of the flask.
- The reflux (boiling) rate determines the overall extraction rate, and some minimum rate must be maintained to ensure complete extraction.
- Emulsions can be a problem. See below for ways to deal with them.

Other liquid-liquid extraction devices While the chemistry and mechanics of liquid-liquid extraction have not changed, many practical variations have improved the speed and convenience of the technique. Two examples of these improvements are the Mixxor™ extractor (New Biology Systems Ltd, Haifa,

Israel) and the VectaSep CLE® system (Whatman, Inc., Clifton, NJ, USA).

The Mixxor™ system (Figure 6) consists of a receiver and piston assembly. The aqueous sample is placed in the receiver (B) with a small quantity of immiscible organic solvent (D). The sample is extracted by moving piston (A) up and down a number of times. After extraction, the plunger is moved to the bottom and the separated organic solvent is forced into the axial chamber (C), where it is easily removed. The entire extraction and separation process is completed in less than 5 min and can provide a concentration factor of 30 or more. Extractors are available for samples with volumes ranging from 2 to 50 mL. This system is more convenient than separatory funnels, although at the expense of some flexibility in sample and extraction solvent volumes. Also, the design precludes the use of heavier-than-water solvents.

The VectaSep CLE® system (Figure 7) is particularly useful for smaller samples. The extraction solvent is placed in the larger tube. The sample (1.5 mL) is added to the sample dispenser, which is then placed in the extraction tube and centrifuged, typically for 10 min at 3500 rpm. Centrifugal force pushes the sample through a dispersion membrane in the bottom of the sample dispenser, causing the sample to emerge as small droplets which travel along

Figure 6 Mixxor™ extraction device. (A) Upper chamber; (B) sample reservoir; (C) axial chamber; (D) organic solvent. (Reproduced with permission of New Biology Systems Ltd.)

Figure 7 VectaSep CLE extraction system. (Reproduced with permission of Whatman, Inc.)

the inside of the tube to the bottom. After centrifugation, the sample dispenser is removed and the separating cup is added to locate the phase separation boundary. Evaporation of the upper organic layer then deposits extracted analytes in the separating cup, where they can be readily redissolved in an appropriate solvent. Although sample size and extraction solvent choices are somewhat limited, this system makes clever use of the extraction principles discussed earlier. In this case, the sample is passed through the extraction solvent (a reverse of the other methods) in small droplets, increasing surface area (kinetics) and offering a very favourable phase ratio.

These systems offer advantages in terms of sample handling, safety and efficiency considerations. So, despite their limitations, both of these systems, and others like them, merit consideration as a replacement for the more traditional techniques.

Emulsions No discussion of liquid–liquid extraction would be complete without mention of the emulsion problem. Emulsions are a mixture of two nor-

mally immiscible phases that won't separate in practice. This problem is often caused by the presence of surfactants or solids at the phase interface, high viscosity of one of the phases, or a small phase ratio (not enough organic phase). Although each emulsion is unique, one of the following remedies will often result in separation into two distinct layers:

- Wait: many emulsions will disappear with sufficient time.
- Gentle mechanical agitation/stirring with a glass rod or spatula.
- Immersion in an ultrasonic cleaning bath.
- Add 'a salt': this makes the aqueous phase less like the organic phase.
- Increase the phase ratio: add more organic phase.
- Pass through a bed packed with glass wool or diatomaceous earth.
- Centrifuge.
- Freeze the aqueous layer with dry ice/acetone or liquid nitrogen, then simply pour off the organic layer.

Liquid–Solid Extraction Techniques

Soxhlet techniques The Soxhlet extractor (Figure 8) is one of the oldest extraction systems available but is still very common. A solid sample is placed in an extraction thimble inside the middle chamber. Upon boiling, the solvent vapours from the bottom flask travel up to the condenser and then drip through the sample. The sample is soaked in solvent (a two-phase distribution equilibrium), which then returns to the flask when the liquid reaches the top of the siphon. The sample is exposed to fresh solvent after every siphon cycle, usually at a rate of about six cycles per hour. Typical extraction times are 6–24 h. Once assembled and operating, there is little that can go wrong with this system. However, operators must be aware of the following general hints:

- Proper cycling is required: the rate (cycles per hour) is usually specified in the method, and the operator must ensure that the unit siphons in distinct events rather than continuously draining.
- Solvent level in the thimble: if too high, sample may be lost from the thimble, contaminating the extract.
- Moisture content: dry samples work best; add a drying agent to remove free moisture.

The system requires a large volume of organic solvent, and extraction time is long. Despite these limitations, the Soxhlet extractor is still in widespread

Figure 8 Soxhlet extractor. (Reproduced with permission of ACCTA, Inc.)

use, primarily because of its excellent reputation for providing complete extraction. Indeed, Soxhlet values are often used as the standard against which other extraction methodologies are compared.

Modified Soxhlet extractors The lengthy Soxhlet extraction times have prompted the development of modified extractors, such as the Soxtec[®] system (Foss Tecator AB, Höganäs, Sweden). The sample is placed in an extraction thimble, but the thimble is then directly immersed in boiling solvent, rather than bathed in cooler condensed solvent. The increased temperature means faster extraction kinetics. After about 1 h equilibration, the sample is removed from the solvent and flushed with fresh condensed solvent for an additional hour. The apparatus even allows

the evaporation and collection of solvent, further improving efficiency. These alternatives offer considerable advantages in terms of time and solvent use, and results are generally comparable to the traditional method.

Solid-phase extraction Solid-phase extraction (SPE) is an alternative to liquid-liquid extraction where the extraction solvent is replaced with a solid sorbent. The sorbent is usually packed into a cartridge (Figure 9) that can vary in size from about 1 mL to more than 50 mL. The quantity of sorbent can range from about 500 mg to 10 g. Extraction is accomplished by forcing the aqueous sample past the sorbent (via vacuum or pressure), causing analytes in the sample to be sorbed. This two-phase distribution is similar to the partitioning that occurs in chromatography. After the sample has passed through the sorbent bed, the sorbed analytes are eluted with a strong solvent, such as methanol, acetonitrile or carbon disulfide.

The SPE process involves the following sequential steps:

- Conditioning/cleaning of the sorbent with an organic solvent such as methanol
- Extraction of the sample.
- Air drying or rinsing to remove any remaining sample.
- Elution of analytes using a strong organic solvent.

SPE offers three primary advantages over conventional liquid-liquid extraction: reduced solvent usage, extraction speed and selective chemistry. In an ideal method, only a few millilitres of organic solvent may be necessary for an extraction and it is possible to extract and elute 10 100-mL samples or more in as little as 15–20 min. Finally, by varying the nature of the sorbent, it is possible to achieve selective extraction and/or selective elution. For example, a minor change in bonded phase from a C₁₈ phase to a C₈ phase can actually result in a significant change in selectivity. The shorter chain C₈ phase is less retentive towards more hydrophobic molecules and exposes somewhat more of the polar character from the underlying silica. This trend can be extended using even shorter aliphatic bonded phases or by adding a polar functional group to the chain (e.g. cyano- or phenyl-). There are no analogous series in liquid-liquid systems.

There are a host of sorbents available, including more polar functional groups, polymer-based, ion exchange, affinity and chelating materials. Nearly every liquid-liquid extraction method has an SPE counterpart, and almost all provide equal if not better

Figure 9 Solid-phase extraction (SPE) cartridge design. (Reproduced with permission of ACCTA, Inc.)

results, with considerably less effort. It should also be noted that SPE can be performed on nonaqueous samples using a polar sorbent, but this application is usually used for sample clean-up rather than extraction.

Finally, it is important to note SPE's limitations:

- High particulate samples will often plug the frits.
- Extracting capacity (total extractable mass) is more limited than with conventional solvent extraction.
- Reproducibility (batch-to-batch) can be a problem, although this is less of a concern now than during early development of the technique.

Membrane disc extraction Membrane extraction discs, first sold under the brand name Empore® (3M, St Paul, MN, USA), are an alternative SPE system. In the membrane discs the sorbent is enclosed in a support network rather than simply being packed into a cartridge. The unique Empore® design consists of 90% (w/w) sorbent particles (8–10 μm diameter), in a network of polytetrafluoroethylene fibrils, in a disc format that resembles a thicker version of conventional synthetic membrane filters. A typical disc is about 0.5 mm thick with diameters ranging from 1 to 90 cm.

A membrane disc extraction method would typically consist of the following steps:

- Pre-washing the disc with the final eluting solvent.
- Pre-wetting the disc with methanol or some other

solvent that is miscible with the sample (which is usually aqueous).

- Extraction, i.e. drawing the sample through the disc.
- Elution of analytes, which involves a soak with the elution solvent for a period of time, followed by elution with the aid of a vacuum. This elution step may be repeated with different solvents if necessary.

Membrane discs have the same advantages over liquid–liquid extraction as SPE but are superior to conventional SPE because the extraction rate is faster; flow rates of 100–200 mL min⁻¹ are typical. The small particles also provide greater capacity and uniformity of packing. Unfortunately, the discs are more sensitive to the presence of particulates, so a pre-filter is often necessary.

Early applications of membrane discs focused on environmental analysis, where large sample sizes made the fast extraction rates attractive. Membrane discs can also be formulated into SPE-like cartridges, allowing the efficient processing of small clinical samples (e.g. serum, urine, etc.). Use of membrane disc applications continues to grow, although the number of reported applications is not as high as SPE, due to the relative age of the two techniques.

Solid-phase microextraction Solid-phase microextraction (SPME) is another version of liquid–solid extraction techniques. In this system, the extraction

Figure 10 Solid-phase microextraction system. (Reproduced with permission of ACCTA, Inc.)

phase consists of a fused silica fibre coated with a sorbent (e.g. dimethylsilicone or other immobilized polymer) with thicknesses ranging from about 10 to 100 μm (Figure 10). The fibre is placed in contact with the liquid or gas sample and analytes are sorbed on to the phase, from which they are directly desorbed into a chromatograph.

Unlike the other techniques discussed here, SPME is a completely solvent-free extraction method. The extraction step tends to be rapid, usually requiring 10–20 min, and desorption can take only a few seconds. Thus, a fast analysis with a good lower limit of detection is possible, since the entire extract is analysed. Furthermore, the selectivity and extractability can be affected by changes in fibre chemistry as well as solution pH, ionic strength, etc. Sampling by immersion in the sample or extraction from the headspace above the liquid (often a faster extraction) provides additional flexibility. However, SPME, by its nature, is not applicable to as wide a range of samples as other techniques, and there are currently a more limited number of sorbents available compared to SPE. However, SPME offers some unique advantages that make it an attractive alternative for many applications.

Pressurized Fluid Extraction

So far, each extraction medium discussed has been either a conventional liquid or solid, each performing its function at or near room pressure and at or below the boiling point of the liquid phase. Experimentally, these conditions are easiest to attain in the laboratory and require relatively unsophisticated equipment. Unfortunately, in some cases these conditions can also result in slow extraction kinetics and/or incomplete extraction because of the (relatively) mild conditions employed. Such problems can often be solved

simply by maintaining the extraction fluid at a higher pressure so that higher temperatures can be used. This can result in a dramatic improvement in extraction efficiency. In addition to the pressurization of conventional solvents in a closed vessel, supercritical fluids may also be used at high temperature and pressure.

Accelerated liquid extraction As noted earlier, increased temperature improves solubility and extraction kinetics, and increases the vapour pressure. In addition, an increase in applied pressure causes an increase in the boiling point of a liquid. Logically, then, one would expect improvement in extraction results at higher applied pressure, where the increased boiling point would then allow liquid extractions above the normal boiling point of the solvent. This approach has been successfully applied in two different ways.

In the first method, called microwave-assisted solvent extraction (MASE), the sample and extraction solvent are placed in a sealed vessel, usually constructed of polytetrafluoroethylene or other inert polymer. When placed in a microwave field, polar materials (e.g. water) absorb energy and the sample heats up. Since the vessel is closed, the pressure also increases, resulting in a significantly elevated boiling point. For example, hexane–acetone mixtures can be used at 115°C, which is more than 40°C above the boiling point of either solvent. The increased temperature has several beneficial effects on the extraction, such as increased solubility, faster diffusion, reduced viscosity and reduced surface tension (increased wettability).

This approach is also used for sample digestion in inorganic analysis, and succeeds for the same reasons – temperature-related improvements in reaction rates.

The second approach uses conventional electrical conduction heating in a sealed stainless steel vessel (Dionex Corporation, Salt Lake City, UT, USA) to accomplish the same effect. With this equipment, the pressure and temperature can be set independently, whereas in the MASE process the pressure increase results from the temperature increase.

Both methods allow Soxhlet-type extractions to be completed in 30 min or less and require small solvent volumes. This approach has received widespread acceptance because it draws from existing experience with organic extraction solvents. The basic chemistry of the extraction does not change significantly, only the rate. In theory, then, any liquid solvent-based extraction method could be adapted for accelerated liquid extraction.

The primary disadvantages involve the safety aspects associated with the use of organic solvents at high temperatures and pressures. In addition, the same process that enhances analyte extraction may also cause extraction of other unwanted components from the matrix. However, the reductions in solvent use and extraction time make accelerated liquid extraction an attractive alternative to unpressurized techniques.

Supercritical fluid extraction As the temperature and pressure on a compound are raised, a point is reached, called the critical point, where the substance is no longer a gas or liquid, but has properties intermediate between these two states. Supercritical fluids are good solvents with gas-like viscosities and diffusivities and no surface tension.

Carbon dioxide is the most popular choice for a supercritical fluid, because of its relatively low critical point (31°C, 73 atm). Supercritical fluid extraction (SFE) then involves placing the sample in a high pressure vessel and contacting the sample with the supercritical fluid. Extraction temperature can be varied from about 40°C to more than 150°C while pressures may be adjusted between 100 and as high as 680 atm or more. Since carbon dioxide is actually a nonpolar fluid, 10–20% of polar modifiers such as methanol can be added to improve the range of solubilities. A typical extraction will be complete in less than 20 min.

SFE receives much attention because the extractions are fast and, with carbon dioxide as the extraction fluid, evaporation of the extracting medium is spontaneous upon decompression to atmospheric conditions. The ability to control extracting power, through changes in temperature, pressure and modi-

fier, offers more selectivity and flexibility than with liquid solvents. While SFE is not a universal replacement for liquid solvent-based methods, it is clearly the best choice for many specific applications, especially foods, natural products, polymers and environmental samples.

Final Comments

Analytical extraction (and sample preparation in general) has returned to its rightful place as an equally important part of the analytical method. There are many options available to achieve extraction, depending on the type and size of sample as well as other more practical considerations. The laboratory worker can choose from 100-year-old techniques that still provide excellent results, or instrumental-based technologies that offer faster extractions on smaller samples.

The extraction step, as a distinct part of the analytical method, will retain its importance as long as chromatographic procedures are used for quantification. The objective of moving the analytes from the sample to the point of quantification will still be required. Future research is likely to focus on better ways of accomplishing this movement, resulting in reduced solvent usage and sample size, automation and online transfer of extracts to subsequent processing and quantification steps. But throughout these changes, it will be important to remember that, although the names may change, the chemistry will remain the same.

Historical Development

Trace elemental analysis is under constant development and the challenging analyses of today become the routine of tomorrow. Despite recent and rapid advances in analytical instrumentation, it is still necessary in many applications to use separation and preconcentration techniques prior to the analytical determination. Typically, the reason for performing a separation and/or preconcentration step is to bring the concentration of the trace element to a detectable level and/or separate it from interfering substances in the sample matrix. Separation and preconcentration are therefore a frequent component of an analytical scheme. Inorganic solvent extractions are also used extensively in industrial applications. Moreover a rapidly developing field, elemental speciation, will depend in part on sophisticated separation techniques such as liquid-liquid inorganic extractions.

Inorganic solvent extractions have been known and performed since the nineteenth century. The extraction of uranyl nitrate into diethyl ether was reported in the 1840s, but it was some time later before quantitative understanding of the inorganic liquid-liquid extraction distribution equilibria was forthcoming. Nernst presented the thermodynamical explanation of the distribution in the 1890s. Chelate extraction was also developing at this time, most notable was the use of 1,5-diphenylcarbohydrazide which chelated with chromium. The work of Fisher in the 1920s with dithizonates is noteworthy; this group studied the distribution of the elements as a function of reagent concentration, metal, complexing agents and pH. During this time, a wide array of solvent extraction methods was developed.

Rapid and distinguished progress in inorganic extractions occurred during World War II, most as part of the 'Manhattan Project' research in atomic energy. One of the most significant applications of liquid-liquid extraction in inorganic chemical technology was the separation of uranium and plutonium from nuclear reaction fission products in the late 1940s. Later, inorganic extractions replaced ion exchange at the beginning of the nuclear fuel cycle for separating uranium from other leach liquors.

Hydrometallurgical applications of liquid-liquid inorganic extractions are numerous and remain the contemporary choice of separation for many processes today. In addition, as environmental regulations develop, increased interest in recovery methods for metals from a variety of waste streams will no doubt renew interest in metal separation techniques.

The prevailing industrial use of inorganic solvent extraction includes the separation of the lanthanide (III) ions. Individual lanthanides are widely used in many of today's 'high-technology' applications for example, lasers (neodymium in yttrium-aluminum garnet), superconducting materials, specialty ceramics, catalyst, the nuclear industry and colour video phosphors.

Inorganic Processes

Solvent extraction, ion exchange, volatilization and precipitation are the most commonly used separation approaches for trace elemental analysis. Inorganic preparation schemes generally follow a flow diagram, as shown in Figure 1.

The processes by which extraction of inorganic compounds occur using organic solvents are varied and may be relatively involved. Consequently, attempts to classify inorganic extraction processes are difficult. Attempts have been made, based on the identity of the extracted compound, or of the extracting agent, or pH of the extraction solution. For the purposes of this chapter, a simple subdivision will be adopted based on the extraction reagent used.

Extraction Considerations

The need for separation and/or preconcentration in trace metal analyses are fundamentally related to available instrumentation and instrumental

capabilities. Basically, separation and/or preconcentration are needed when one of the following situations occurs: concentration of analyte is below the sensitivity of the instrumental method; interferences exist in the sample (relative to the instrument to be used); or physical or chemical states of the sample are not appropriate for the instrument. Sensitivities for elements varies with the instrumental method and are relative to matrix type; however, a general listing of sensitivities of commonly used analytical equipment is given in **Table 1**.

The impetus for doing an extraction will therefore depend on the availability of instruments and the capability of the instrument relative to the matrix type (i.e. interferences). Inorganic extraction schemes are typically instrument specific. Although instrument development has significantly reduced detection limits, availability of some of the more state-of-the-art equipment is still limited to specialized or well-equipped laboratories. The need for separation and preconcentration therefore still exist. Speciation studies will also continue to support development and research into inorganic separations from complex matrices.

Because atomic absorption spectrometry (AAS) is readily available, but the detection limits are high in relation to today's needs, there are numerous solvent extraction methods available for metals in AAS analysis. Several excellent sources are listed in Further Reading; these have lengthy tables of inorganic extraction schemes.

Theory and Equations of Inorganic Solvent Extraction

The solvent extraction process to separate and/or preconcentrate an analyte of interest is performed by using two immiscible solvents. A complex (typically neutral in charge) is formed with the element of interest, typically in an aqueous solution and will partition into a mutually insoluble (organic solvent) phase. The Nernst partition (or distribution law) states that at equilibrium a given solute will be distributed between two essentially immiscible liquids according to the following equation:

$$K_D = \gamma_o[A]_o / \gamma_{aq}[A]_{aq}$$

where K_D is the distribution coefficient (also called the partition coefficient) and $[A]$ is the concentration of the analyte, γ are activity coefficients, subscript 'o' denotes organic phase and the 'aq' subscript denotes aqueous phase. The above equation holds true in only the most rigorously well-defined thermodynamic systems. For simplicity the relationship assumes that no side reactions occur in either the aqueous or organic phase and that no stable intermediates are formed with the analyte (e.g. metal) of interest. From a practitioner's standpoint, the total amount of analyte (e.g. metal) transferred from one phase to the other is of most interest. An empirical distribution ratio, D , is defined by the simplified relationship given below:

$$D = [A_T]_o / [A_T]_{aq}$$

where $[A_T]_o$ includes all (T = total) complexes of the analyte of interest in the organic phase and activity coefficients are assumed unity. The assumption of $\gamma = 1$ for chelating extractions is reasonable. However, for ion-pair extractions where the electrolyte concentration is high, to assume unity for the activity coefficients is a poor assumption. The simplifying relationship is still often employed, however, with the assumption that the (γ_o/γ_{aq}) ratio will remain constant.

The extraction efficiency, $\%E$, which defines the amount of analyte transferred from the aqueous phase to the organic phase, is defined as follows:

$$\% \text{ Extraction} = 100D / \{D + (V_{aq}/V_o)\}$$

where V_{aq} is the volume of the aqueous phase and V_o is the volume of the organic phase. An important property of the above relationship is that the extraction efficiency is independent of the initial analyte concentration. High extraction efficiencies can be achieved when the V_{aq}/V_o ratio is small (that is, small aqueous volumes used with large organic volumes). There is of course a practical limit to this approach. Multiple extractions with reasonable volumes perform better than a single extraction with one large volume. Large values of D , distribution ratio, correspond to high extraction efficiencies (e.g. $D = 100$ then $\%E = 99\%$, $D = 0.1$ then $\%E = 10\%$, for a 1 : 1 volume ratio).

An extraction reaction may be described by the general chemical equation given below:

where A is the analyte of interest (e.g. metal ion) with charge n^+ , HX is the extracting agent (e.g. chelating agent). Note, that extracting agents are often acidic. From the following extraction reaction the equilibrium constant, K_{ex} is:

$$K_{ex} = [AX_n]_o [H^+]^n / [A^n]_{aq} [HX]^n_o$$

By substituting the distribution ratio, D , the equation simplifies to:

$$K_{ex} = D \{ [H^+]^n / [HX]^n_o \}$$

hence:

$$D = K_{ex} [HX]^n_o / [H^+]^n$$

The logarithmic form for the distribution coefficient is then:

$$\log D = \log K_{ex} + npH + n \log [HX]_o$$

From this model, for a given system, the degree of extraction increases as the concentration of the chelate $[HX]_o$ increases. Extraction increases with increasing pH (decreasing hydrogen concentration) in the aqueous phase. A one unit increase in pH results in a factor of 10 increase in the distribution coefficient for $n = 1$; for $n = 2$, the distribution coefficient increases by a factor of 100. Hydrolysis of the metal ion and decreased solubility of the chelate occur at high pH limiting this general approach.

Plots of $\log D$ versus pH (or $\%E$ versus pH or versus $pH_{1/2}$) are often used to define extraction systems. These types of plots produce sigmoidal curves, with the overall position relative to the pH axis dependent on K_{ex} with the slope $= n$. For purposes of comparison, if $D = 1$ (i.e. $E = 50\%$) and $[HX]_o = 1$, the pH is constant and equal to $\log K_{ex}/n$. This term is referred to as $pH_{1/2}$, and is characteristic of the extraction process. Analyte/chelate agent values of $pH_{1/2}$ are often cited and are used as a measure of the feasibility of separating two analytes.

Further theoretical discussion is beyond the scope of this chapter but includes topics on solvent properties, such as the solvent Hildebrand parameter, solvent dielectric constant, and complex properties such as the complex size, polarity and polarizability, as well as pH, temperature and reaction kinetics.

Inorganic Solvent Extractions

The essential prerequisite for an element to be extracted from an aqueous solution is that it be part of a neutral complex. Charge neutrality reduces the electrostatic interactions between the element (analyte of interest) complex and water and therefore lowers the solubility of the complex in water. Consequently, the neutral complex can be extracted into the less polar organic solvent. General attributes and chemical properties that can facilitate separation are: charge neutrality, increase size of complex formed and incorporation of hydrophobic or organophilic properties. These general attributes can be accomplished by several mechanisms including the element associated with naturally occurring complexants, chelate complexes formed with analyte and ion-associated (ion-paired) complexes. All three mechanisms can and will form a neutral complex with the analyte of interest. Depending on the ligands (complex associated with the element) other chemical properties such as complex size and hydrophobic/organophilic properties can be incorporated.

Extraction Schemes

Classification schemes are numerous and no one scheme covers all systems. The most common

schemes are based on the form of the extracted element that transfers into the organic phase. This simplified classification scheme is adequate for the discussion here. However, even with simple schemes the categories are not exclusive, and some extraction agents could be classified into other categories. The experimental process of inorganic extraction of a neutral complex, regardless of the type of complex, is essentially the same. The neutral complex's interaction with the aqueous phase, including but not limited to the solubility, depends on the charge and polarity of the overall complex. The first step is to generate a neutral complex with the analyte of interest through one of the mechanisms listed above. A small volume of organic solvent is added to the sample mixture. For example, a 1 L aqueous sample may be extracted into 40 mL of organic solvent. Extraction can be performed in a separatory funnel or by using a mechanical shaker table. The pH of the mixture may need to be manipulated, depending on the exact extraction scheme used. In addition, masking agents may be used to obtain specificity (see below). After mixing, the two phases are separated and the procedure is generally repeated several times. The organic phase is combined from each extraction. The concentration of the elements in the sample is increased by 1–3 orders of magnitude in the organic phase. The extract can then be further pre-concentrated if needed (back-extraction, evaporation, etc.) or analysed directly, for example by flame AAS.

Naturally occurring complexants Elements that can form neutral complexes can already exist in naturally occurring water systems. These complexes are formed essentially with covalent bonding between the element and naturally occurring ligand(s). Ligands are molecules or ions bonded to a central metal ion and tend to be Lewis bases; also included in this category would be undissociated covalent species. Examples of this category would include I_2 and B_2 , the halides of some metals ($GeCl_4$, $HgCl_2$, $AsCl_3$) and oxides of some metals (OsO_4). The extraction of these types of compounds would proceed in the same manner as for chelates and ion-associated complexes.

Chelates A chelate is a type of ligand. A multidentate (*dentate* is Latin for tooth) ligand that uses more than one atom to bind to a metal in a coordination complex, see Figure 2. The metal is the electron-pair acceptor and the chelating agent the electron-pair donor. When binding to the metal ion, the chelate (ligand) forms a ring of atoms, of which the metal is one member. The chelate complex charge exactly neutralizes the charge on the metal ion. Most rings contain > 4 and < 8 atom members; the most stable

Figure 2 Chemical structures of typical chelate-metal complexes.

typically is a 5-membered ring. Bidendate describes a chelate where two atoms from the chelate complex bond to the metal and tridentate would indicate three coordinating atoms. Many chelating extractants are weak acids, therefore, control of pH is important in many extracting schemes.

An exhaustive treatment of every chelate system is beyond the scope of this chapter. Table 2 lists a selection of chelate types with one or two specific chelate agents listed below these. To describe the selectivity of each is not possible in a brief chapter, a sense of the ability of each chelate reagent is given by listing the wide range of complex-forming metals that are possible. Detailed information about the selectivity, solvent and other experimental conditions can be found in the references listed in Further Reading. The list in Table 2 include inorganic extraction procedures for a wide array of instrumental methods including: flame AAS, electrothermal (ET)-AAS, inductively coupled plasma-atomic emission spectroscopy, (ICP-AES), neutron activation analysis (NAA), spectrophotometric, chromatographic, flame photometry, and polarography. In addition, most of the chelate groups listed in Table 2 are compatible with more than one organic solvent. Solvent flexibility in an analytical scheme allows an extended range of instrumental methods which can be used for the determination.

Inorganic extraction, utilizing chelates, for analytical separation and/or preconcentration has been exploited for many instrumental systems. For flame AAS analysis, often the inorganic solvent extraction is designed to increase the concentration of elements of interest and, most importantly, reduce the concentration of alkali and alkaline earth elements (i.e. leave most of them in the aqueous phase). This separation

Table 2 A select list of inorganic extraction systems

	<i>Metals extracted</i>
<i>Chelating agents</i>	
<i>Oxines</i>	
-8-Hydroxyquinoline -(and derivatives)	> 50 metals

-HF	> 50 metals
-HI	> 50 metals

is especially necessary for many natural water samples such as seawater, brines, etc. Trace element analyses of clinical samples such as blood, urine, etc., also benefit from inorganic extraction for flame AAS analysis as well as other determination techniques (ET-AAS, ICP-AES, etc.). Radiochemistry separations for NAA also often use inorganic extraction techniques that utilize chelating schemes.

Extraction schemes have also been developed which leave the analyte of interest in the aqueous phase and remove interferences through the organic phase. This technique has limited applicability owing to the limited solubility of the (starting reagent) chelate in organic solvents.

Ion association (ion pair) Neutral complexes can be formed through ion association (ion-pair) and extracted from an aqueous solution into an organic solvent. Ion association inorganic extracts encompass a wide range of extraction schemes. General sub-groupings include chelated ion pairs, nonchelated ion pairs and halide-cation ion-pairs. The halide-cation pairs are typically extracted into oxygen-containing solvents, such as methyl isobutyl ketone, diethyl ether and alcohols. A select list of ion pair extracting agents is given in Table 2.

Maximizing the coulombic forces of attraction between the ion pairs facilitates extraction of the ion pairs. The dielectric constant of the solvent is a large contributor to the overall extractability of a scheme. Enhancement of the extraction of ion-associated complexes is increased by the addition of electrolytes, called 'salting-out'. The salting-out effect may be attributed to the increase in anion concentration, as well as the decrease of the dielectric constant of the aqueous phase. Complexes can be formed by ligands coordinated to the metal and an appropriate counter anion that neutralizes the total charge. One of the ions (either the complexed ligand or the anion) typically contains a large hydrophobic group(s) which further enhances extraction of the ion pair into the organic phase.

Factors Affecting Inorganic Solvent Extractions

Control of pH is critical to ensure conditions are favourable for the formation of the desired complexes. The extraction specificity needed influences the acceptable range of pH. Many inorganic extraction schemes use buffers. The lack of a buffer in an inorganic extraction should be viewed with suspicion, since the quantity of metal extracted is strongly pH dependent. In addition, chelating agents will alter the pH of the solution. Several buffers have been used for inorganic extractions for AAS determination, including borate, phosphate, citrate, acetate and formate. Acetate should not be used if lead or silver or other stable metal acetates are to be determined. Buffers can be a significant source of contamination, as can any unpurified reagent added to a sample.

The nature of the solvent is of special importance for inorganic extractions. There are several criteria which should be evaluated when choosing a solvent for an inorganic extraction. The solvent should have the following characteristics:

- Extracts the desired metal chelates
- Immiscible with aqueous solution (i.e. low solubility in water); for convenience, density > water if the sample is drawn off
- Does not form emulsions

- Compatible with the analytical determination technique
- Environmentally safe and nontoxic
- Available in an acceptably uncontaminated state.

In the case of flame AAS, ketones or esters are commonly used extraction solvents. The list of organic solvents used in inorganic extractions is extensive.

Masking Agents

When the desired specificity for separation cannot be controlled sufficiently by pH modification, addition of a masking agent will frequently be used. Masking agents are complexing agents that form water-soluble complexes which then compete with the extracting agent. The masking agents prevent the extraction of the metals they react with, by forming water-soluble complexes (strong polar complexes) which remain in the aqueous phase. Some extracting agents are specific and many others can be made specific using pH control and/or a masking agent. The most commonly used masking agents include cyanide, thiocyanate, thiosulfate, tartrate, carbonate, citrate, fluoride, bromide, iodide and ethylenediaminetetraacetic acid (EDTA). The effectiveness of masking agents is pH specific, ranging from acidic to basic conditions. In some schemes, more than one masking agent may be used.

Applications

Inorganic extractions are used in both analytical and industrial fields. Chelates form an important part of inorganic extractions and have extensive application in many areas of science and industry.

As discussed above, analytical applications include the separation and/or preconcentration of an analyte for determination. Another analytical application is the use of inorganic extraction techniques for reagent purification by removing trace metals (e.g. purification of aqueous buffers). Extraction of metals into nonpolar organic phases crosses many scientific disciplines. For example, crown ethers are used extensively as phase transfer catalysts. Crown ethers extract an element (e.g. K^+) from the aqueous phase into an organic phase. The K^+ ion is engulfed (chelated) in the centre of the crown ether. A class of antibiotics, the ionophores (e.g. nonactin, valinomycin, gramicidin, etc.) work much like crown ethers: they alter the permeability (distribution) of bacterial cells to metal ions and thereby disrupt their metabolism.

An example of a large-scale inorganic metallurgical extraction, is the Purex process used to extract ura-

nium isotopes and plutonium. Once the uranium ore (e.g. carnotite) is crushed, it is concentrated by physical means; the uranium is then further concentrated by flotation methods. The ore is then roasted and leached with sulfuric acid (often with an oxidizing agent) and precipitates as sodium diuranate, a bright yellow solid called 'yellowcake'. This solid dissolves in nitric acid producing uranyl nitrate. The inorganic solvent extraction (Purex process) extracts the uranyl nitrate from the aqueous solution into tributyl phosphate in an inert hydrocarbon diluent: the impurities remain in the aqueous phase.

The aim of speciation studies is to identify and quantify all species that together combine to comprise the total element concentration. This is typically achieved by physicochemical techniques. A range of physicochemical separation techniques has been applied to speciation studies, including inorganic solvent extraction.

Inorganic chelate extractions are used extensively in industrial applications. A brief listing includes the following applications:

- Metallurgical extraction
- The chelate: (EDTA)
 - used in water softeners
 - boiler scale removal
 - industrial cleaning
 - soil metal micronutrient transport
 - food preservation
- The chelate: nitrilotriacetic acid (NTA)
 - similar applications to those listed for EDTA
- Ion exchange resins can be chelates
 - water purification processes
- Zeolites are a type of chelating ion exchange resin
 - water purification processes

Future Developments

Although instrument development has had a significant impact on inorganic extractions and the direction of research on separation and preconcentration techniques, there remains an extensive need and interest in inorganic solvent extraction techniques. One area which is currently under intense investigation is speciation. Chemical-physical methods of separation incorporating inorganic extractions remain an important part of this field. Another area of development is the recovery and removal of metals from industrial waste streams.

Introduction

Common extraction techniques for solid matrices include Soxhlet extraction, sonication extraction, supercritical fluid extraction (SFE), microwave-assisted extraction (MAE), and accelerated-solvent extraction (ASE).

Soxhlet extraction allows use of large amount of sample (e.g. 10–30 g), no filtration is required after the extraction, the technique is not matrix dependent, and many Soxhlet extractors can be set up to perform in unattended operation. The most significant drawbacks of Soxhlet extraction are: long extraction times (e.g. up to 24–48 h), large amount of solvent usage (300–500 mL per sample), and the need for evaporation after sample extraction.

Sonication extraction is faster than Soxhlet extraction (30–60 min per sample) and allows extraction of

large amount of sample with a relatively low cost, but it still uses about as much solvent as Soxhlet extraction, is labour intensive, and filtration is required after extraction.

The newer extraction techniques such as SFE, MAE, and ASE are very attractive because they are a lot faster, use much smaller amounts of solvents, and are environmentally friendly techniques. For example, SFE uses carbon dioxide or modified carbon dioxide (e.g., carbon dioxide containing a small amount of an organic solvent known as modifier) for extraction. Carbon dioxide is a nontoxic, nonflammable, and environmentally friendly solvent. Furthermore, the extraction selectivity can be controlled by varying the pressure and temperature of the supercritical fluid and by the addition of modifiers.

MAE uses microwaves that can easily penetrate into the sample pores causing the solvent trapped in the pores to heat evenly and rapidly. In contrast to conventional heating where it takes a long time for the vessel to heat and then transfer its energy to the

Introduction

Common extraction techniques for solid matrices include Soxhlet extraction, sonication extraction, supercritical fluid extraction (SFE), microwave-assisted extraction (MAE), and accelerated-solvent extraction (ASE).

Soxhlet extraction allows use of large amount of sample (e.g. 10–30 g), no filtration is required after the extraction, the technique is not matrix dependent, and many Soxhlet extractors can be set up to perform in unattended operation. The most significant drawbacks of Soxhlet extraction are: long extraction times (e.g. up to 24–48 h), large amount of solvent usage (300–500 mL per sample), and the need for evaporation after sample extraction.

Sonication extraction is faster than Soxhlet extraction (30–60 min per sample) and allows extraction of

large amount of sample with a relatively low cost, but it still uses about as much solvent as Soxhlet extraction, is labour intensive, and filtration is required after extraction.

The newer extraction techniques such as SFE, MAE, and ASE are very attractive because they are a lot faster, use much smaller amounts of solvents, and are environmentally friendly techniques. For example, SFE uses carbon dioxide or modified carbon dioxide (e.g., carbon dioxide containing a small amount of an organic solvent known as modifier) for extraction. Carbon dioxide is a nontoxic, nonflammable, and environmentally friendly solvent. Furthermore, the extraction selectivity can be controlled by varying the pressure and temperature of the supercritical fluid and by the addition of modifiers.

MAE uses microwaves that can easily penetrate into the sample pores causing the solvent trapped in the pores to heat evenly and rapidly. In contrast to conventional heating where it takes a long time for the vessel to heat and then transfer its energy to the

solvent, MAE is very fast since the heat is transferred directly to the solvent (provided that the solvent absorbs microwaves). MAE is promising because: it is fast (e.g. 20–30 min per batch of as many as 12 samples); MAE uses small amounts of solvents as compared to Soxhlet and sonication extraction (30 mL in MAE versus 300–500 mL in Soxhlet extraction); it allows full control of extraction parameters (time, power, temperature); stirring of the sample is possible in MAE; allows high temperature extraction; and no drying agents are needed in MAE since water absorbs microwaves very fast and thus can be used to heat up the matrix. MAE has several drawbacks that contributed to its slow acceptance such as: extracts must be filtered after extraction, which slows down the operation; polar solvents are needed; cleanup of extracts is needed because MAE is very efficient (e.g. ‘everything’ gets extracted); and the equipment is moderately expensive.

Accelerated solvent extraction is a fairly new extraction method that was approved recently by the U.S. Environmental Protection Agency (EPA) as Method 3545. The extraction is done in a closed-vessel at elevated temperatures (50° to 200°C) and pressures (1500–2000 psi). This technique is attractive because it is fast (e.g. extraction time is approximately 15 min per sample), uses minimal solvent (15–40 mL), no filtration is required after the extraction, and the instrumentation allows extraction in unattended operation. At least 24 samples can be processed sequentially and different sample sizes can be accommodated (e.g. 11, 22, and 33-mL vessels are available).

Theoretical Considerations in MAE

Microwaves are high-frequency electromagnetic waves placed between radio frequency and the infrared regions of the electromagnetic spectrum (their frequency range from 0.3 to 300 GHz corresponding to wavelengths of 1 m to 1 mm). In contrast to conventional heating where the heat penetrates slowly from the outside to the inside of an object, in MAE the heating appears right in the core of the body that is being heated, and the heat spreads from the inside to the outside of that body. The microwave energy affects molecules by ionic conduction and dipole rotation. In ionic conduction, the ions in solution will migrate when an electromagnetic field is applied. The resistance of solution to this flow of ions will result in friction and, thus, heating of the solution. Dipole rotation means realignment of the dipoles with the applied field. At 2450 MHz, the dipoles align and randomize 4.9×10^9 times per second; this forced

molecular movement results in molecular ‘friction’ and, thus, heating of the solution.

Selection of proper solvents is the key to a successful extraction. In selecting solvents, consideration should be given to the microwave-absorbing properties of the solvent, the interaction of the solvent with the matrix, and the analyte solubility in the solvent (the principle of ‘like dissolves like’ is still applicable in MAE). The larger the dipole moment of the solvent the faster the solvent will heat under microwave irradiation. For example, hexane (dipole moment is < 0.1 Debye) will not heat, whereas acetone with a dipole moment of 2.69 Debye will heat in a matter of seconds. Thus, a mixture of hexane and acetone is an ideal solvent for compounds of environmental significance, and many applications described here use hexane–acetone (1 : 1).

Other important factors under considerations include: 1. the compatibility between the extraction solvent and the analytical method used in the analysis of the extract (the less polar solvents seem to be preferred for gas chromatographic analysis, whereas the more polar ones for liquid chromatographic analysis and immunoassay techniques) and 2. the selectivity of the solvent. Little has been reported in the literature on the selectivity of MAE because the technique is so efficient that it can not be regarded as a selective extraction technique. ‘Everything gets extracted’ so a cleanup step after the extraction is needed in almost all cases.

When MAE is conducted in closed vessels, the temperature achieved during the extraction will be greater than the boiling points of the solvents. For most of the solvents (e.g. acetone, acetone–hexane, dichloromethane–acetone), the temperature inside the vessel is two to three times the boiling point of the solvent. These elevated temperatures result in improved extraction efficiencies of the analyte from the sample matrix. The reader should refer to **Table 1** for a listing of solvents and their maximum closed-vessel temperatures achieved at 175 psi.

Instrumentation for MAE

The features of commercially available MAE systems are identified in **Table 2**. The equipment (**Figure 1**) used for closed-vessel MAE consists of a magnetron tube, an oven where the individual extraction vessels (closed vessels) are set up on a turntable or rotor, monitoring devices for temperature and pressure, and electronic components. It usually includes specific safety features such as rupture membranes for the extraction vessels, an exhaust fan to evacuate air from the instrument cavity, a solvent vapour detector (monitors the presence of solvent vapour in the

microwave cavity and shuts off the microwave energy whenever solvent vapour is detected in the instrument cavity), an expansion container (the extraction vessels are connected to this expansion container through vent tubing; in case the membrane ruptures, due to increased pressure in the vessel, then vapour is re-

moved through the rupture vent tube), and an isolator located in the wave guide that diverts reflected microwave energy into a dummy load to reduce the microwave energy within the cavity. One manufacturer of microwave equipment uses resealable vessels. In this case, vessels are placed on a sample rotor and secured with a calibrated torque wrench for uniform pressure. If the pressure exceeds the vessel limits, a spring device (Milestone's patented technology) allows the vessel to open and close quickly, thus releasing the excess pressure. These sample rotors are available with (perfluoroalkoxy)polymer (PFATM) and (tetrafluoroalkoxy)polymer (TFMTM) liners with pressure ratings of 435 psi to 1450 psi. Another safety feature which was added to the microwave system is the 'movable wall'. To prevent the door from being blown away, a door frame on spring-loaded, high-impact steel bars was added such that the door moves out and in to release pressure from the microwave cavity.

Typical pressures reached with most closed-vessel systems (first-generation) were 105 psi, but today's technology can handle pressures as high as 1500–1600 psi. A special rotor, which houses six thick-walled vessels capable of working at 1600 psi, is available commercially on several systems, including the CEM's MARS-5, Milestone's Ethos-1600,

and Plazmatronika's UniClever system. In the Milestone system, for example, if the operating pressure inside the vessel exceeds the vessel limits, a special spring device will allow the vessel to open and close, thus reducing the pressure.

The vessels are typically made of microwave transparent materials (e.g. polyetherimide, or TFM) and are lined with perfluoroalkoxy or TeflonTM liners. A new microwave system introduced recently by one

manufacturer uses magnetic stir bars, which allow extraction with polar and nonpolar solvents while agitating the sample and solvent to achieve efficient mixing and improve analyte recoveries.

Figure 2 shows a schematic of CEM's lined digestion vessel with and without temperature and pressure control. Vessel body and cap are made of UltemTM, a polyetherimide. The cap and cover of the control vessel are modified to allow

Figure 2 (A) Standard lined extraction vessel and (B) lined extraction vessel with pressure temperature control.

a pressure-sensing tube and a fibre optic temperature probe. The fibre optic probe is microwave transparent and is positioned in the control vessel using a glass thermal well. Infrared temperature sensors are also used to monitor the temperature inside the vessel. As the turntable revolves, the infrared sensor measures the temperature of each vessel. More detail on the pressure and temperature feedback control can be found elsewhere.

Additional features such as magnetic stirring of the extraction solvent inside multiple sample vessels is possible, at least on one commercial system (Ethos 1600 Labstation from Milestone, Inc.). Moreover, nonpolar solvents, such as hexane, can now be heated at elevated temperatures by use of magnetic stir bars made of Milestone's proprietary fluoropolymer Weflon™. (This polymer absorbs the microwave energy and subsequently transfers heat to the surrounding medium.)

All closed vessel systems that are available commercially are multivessel systems which evenly space the vessels on a carousel or rotor and rotate them through a pattern on 360° oscillating turntable.

Specific Applications for MAE

Selected MAE applications are identified in Table 3.

Polycyclic Aromatic Hydrocarbons (PAHs)

Work done by V. Lopez-Avila *et al.* indicated that PAHs, with the exception of more volatile compounds such as naphthalene, can be extracted quantitatively (recovery > 80%) from soil and sediment matrices with hexane–acetone (1 : 1) at temperatures of 115°C. Typical extraction times for batches of up to 12 samples (5 g each) are 10 min at 100% power (1000 watts). The lower recoveries of naphthalene, acenaphthene, and acenaphthylene were attributed to the presence of water in the soil matrix (to prepare a representative aged soil sample, water was added to the soil matrix to bring its water content to 30%).

Other successful microwave-assisted extractions of PAHs from soils, sediments, and fly ash have been reported with hexane–acetone (1 : 1), acetone alone, dichloromethane alone, dichloromethane–toluene (50 : 50), acetone–petroleum ether (1 : 1), methanol–toluene (9 : 1), and toluene–water.

Dean *et al.* reported on a direct comparison between Soxhlet, MAE, and SFE for PAHs and concluded that the major advantage of MAE is the speed of extraction, but they also acknowledged that without additional cooling after extraction it takes approximately 30 min until the vessels can be opened and extracts processed. Barnabas, Dean and

coworkers also investigated the effects of pressure, temperature, extraction time, and percent of methanol modifier added to the extraction solvent in order to optimize the extraction.

Chee *et al.* reported a 5-min heating at 115°C with 30 mL hexane–acetone (1 : 1) as the optimum extraction conditions for a 5 g sample, conditions which are very similar to those reported by V. Lopez-Avila *et al.*

Optimization of MAE of PAHs using open-vessel technology was conducted by Budzinski *et al.*, who reported that the optimum conditions are 30% water, 30 mL dichloromethane, and 10 min heating at 30 W power. When considering that the time needed to reach the boiling point is about 2 min (for dichloromethane), a heating time of 10 min is more than sufficient to extract PAHs quantitatively from the matrix, especially when adding water which is supposed to cause swelling of the matrix.

Organochlorine pesticides (OCPs)

Onuska and Terry extracted aldrin, dieldrin, and DDT from soils and sediments using acetonitrile, isooctane, or a mixture of isooctane–acetonitrile (1 : 1, v/v) and achieved quantitative recoveries using five or seven 30-s irradiations with microwave energy. They also reported that MAE recoveries increase as the moisture content of the soil increases up to 15%. Fish and Revesz used hexane–acetone as extraction solvent and reported that OCP recoveries improved when changing from 1 : 1 hexane–acetone to 2 : 3 hexane–acetone. The latter solvent has a composition similar to the azeotropic vapour in the Soxhlet extractor.

Lopez-Avila *et al.* extracted 45 OCPs from freshly spiked and 24-h aged soil samples with hexane–acetone (1 : 1, v/v). For the freshly spiked soil, 38 compounds had recoveries between 80 and 120%, six compounds had recoveries between 50 and 80%, and the recovery of captafol was above 120%. For the spiked soil samples aged for 24 h, 28 compounds had recoveries between 80 and 120%; 12 compounds had recoveries between 50 and 80%; three compounds including captafol, captan, and dichlone were poorly recovered; and chloroneb and 4,4'-DDT had recoveries above 120%.

When recoveries from freshly spiked soil were compared to those from aged spiked soil, it was found that the recovery of captafol dropped from 122% to 36%, the recovery of captan dropped from 106% to 21%, and the recovery of dichlone dropped from 78% to 10%. Captafol and captan appear to be quite stable upon irradiation of soil/solvent suspensions, but dichlone was found to disappear upon irradiation

of the solvent. (The recovery of dichlone from solvent was only 5.5% after heating at 145°C for 5 min and 2.6% after 20 min at the same temperature.) Microbial degradation may be responsible for the low recoveries of captafol and captan, whereas in the case of dichlone, it is quite likely that this compound is not stable under the conditions used. Nonetheless, these recoveries are higher than those obtained by Soxhlet or sonication extraction.

Water samples can also be extracted by MAE; however, they have to be preconcentrated first on a membrane disc or some adsorbent material. Chee *et al.* used C₁₈-membrane discs and then extracted the discs with 20 mL solvent (acetone and dichloromethane) in a closed-vessel MAE system at 80°C, 100°C and 120°C for 1, 3, 5 and 10 min. Acetone was found to give higher recoveries than dichloromethane. This approach would allow extremely low detection limits since several discs generated by processing a large volume of sample can be extracted in one vessel.

Vetter and coworkers extracted OCPs from fatty tissues (e.g. seal blubber) with solvents such as hexane and ethyl acetate (1 : 1). To transfer heat to hexane, which is microwave transparent, discs of Weflon™ (2.5 cm in diameter × 0.3 cm thickness) were used in the extraction vessel. The yield of extractable fat and recoveries of OCPs after seven irradiation cycles were comparable to those obtained by Soxhlet extraction. Since ethyl acetate-cyclohexane (1 : 1, v/v) seems to extract more fat than hexane, a gel permeation chromatography step after extraction is a must.

Polychlorinated Biphenyls (PCBs)

MAE of PCBs was reported by Lopez-Avila *et al.*, Onuska and Terri, Chee *et al.*, Pastor *et al.*, Dupont *et al.* and Kodba and Marsel. Lopez-Avila *et al.* used hexane-acetone (1 : 1, v/v) and reported that the average recoveries from typical soil matrices were greater than 70% for the Aroclors 1016 and 1260 and the method precision was better than 7%. Furthermore, there was no degradation of PCBs upon heating of solvent/soil suspensions with microwave energy. Three reference materials and 24 soils from a Superfund site, most of which contained Aroclors, were extracted by MAE and analysed by both GC/ECD and enzyme-linked immunosorbent assay (ELISA). Because ELISA is very sensitive and its detection range is quite narrow, the hexane-acetone extracts were first diluted with methanol and subsequently with the assay buffer (which contained 50% methanol) to bring the Aroclor concentrations to less than 5 ng mL⁻¹. These data indicate excellent

agreement between the certified Soxhlet/GC/ECD data and the MAE-ELISA data (correlation coefficient 0.9986; slope 1.0168) and the MAE-GC/ECD data and the MAE-ELISA data (correlation coefficient 0.9793; slope 1.0468).

Other solvents used successfully to extract PCBs from environmental samples include isooctane, acetone and dichloromethane, and toluene-water.

Phenols

MAE of phenolic compounds was reported by Lopez-Avila *et al.*, Llompart *et al.*, Chee *et al.* and Egizabal *et al.* Acetone-hexane seems to be the preferred solvent for 16 phenolic compounds and dichloromethane, acetone-petroleum ether (1 : 1) were reported to work well for extraction of nonylphenol. The only compounds found to degrade during MAE are 2,4-dinitrophenol and 4,6-dinitro-2-methylphenol. MAE recoveries for phenolic compounds are usually higher than the classical extraction method recoveries, and the method precision is significantly better for MAE (e.g. coefficient of variation of 3% for MAE as compared to 15% for Soxhlet and 20% for sonication).

Herbicides

Imidazolinones (e.g. imazapyr, imazetapyr, imazethapyr, imazaquin, etc.) are extracted from soil with 0.1 M ammonium acetate/ammonium hydroxide (pH 9–10) in a 10-min extraction. A variety of soil samples fortified at 1 to 50 p.p.b. exhibited an average recovery of 92% (standard deviation 13%).

Triazine herbicides have been successfully extracted from soil by MAE with water, methanol, acetone-hexane (1 : 1), dichloromethane, acetonitrile-0.5% ammonia in water (70 : 30), dichloromethane-water (50 : 50), methanol-dichloromethane (10 : 90). Water seems to be preferred since it is very polar solvent and can interact strongly with polar matter in soils to enhance the desorption of triazines; it is a cheap, safe, and environmentally friendly solvent; and it heats up very quickly when irradiated with microwave energy microwave energy. Xiong *et al.* reported that direct heating of soil with water gave a 73.4% recovery for atrazine from soil and, therefore, stated that 'MAE is not only a simple heating'.

Organotin and Organomercury Compounds

Methods reported in the literature for the determination of organotin compounds in soils use extraction with organic solvents in the presence of complexing agent, or leaching with acetic or hydrochloric acid assisted by sonication or some sort of shaking.

Open-vessel MAE was recommended to accelerate the leaching with 50% acetic acid aqueous solution, and the data showed that a 3-min irradiation at 60 W was sufficient to recover tributyl tin from certified reference sediments. Ethanoic acid (0.5 M in methanol) was also reported. When dealing with biological matrices (e.g., tuna tissue, mussel tissue), solubilization with tetramethylammonium hydroxide (TMAH) for a 3 min at 90°C, 115°C, and 130°C in a closed vessel was demonstrated to be as efficient as the hot-plate procedure. Schmitt *et al.* reported on the integration of the solubilization step with the derivatization/extraction step by using 11 M acetic acid for solubilization and NaBEt₄ for derivatization using an open vessel MAE system.

Organomercury compounds can be extracted from sediments with 6 M hydrochloric acid at 120°C for 10 min in closed vessel or 2 M nitric acid and 2 M hydrochloric acid after 3 min irradiation at 60 W in open vessel. Pure acetic acid and 1 M sulfuric acid could only extract 85% and 55%, respectively. Microwave-assisted digestion of the biological tissue with 25% TMAH for 2–4 min at 40–60 W gave quantitative recovery of both organomercury and inorganic mercury.

Additives in Polymers

Antioxidants such as the Irganox 1010, Irganox 1076, and Irgaphos 168, which are added to polymers to protect them during end-use applications, can be extracted with > 95% efficiency by MAE with *n*-heptane–acetone in a few minutes. Higher temperatures (e.g. 140°C) were used by Jordi *et al.* with cyclohexane–chloroform–triethylamine (45:45:10) to dissolve polyethylene and extract compounds such as Tinuvin 770, Tinuvin 622, Tinuvin 144, and Chimisorb 81.

Natural Products

Extraction of oils from mint leaves and other materials of biological origin is a patented process known as the 'microwave-assisted process'. Other reports on MAE of natural products include that of Young, Bichi *et al.* and Mattina *et al.* Young extracted ergosterol from fungi and spores by MAE with methanol and 2 M sodium hydroxide. Bichi *et al.* extracted pyrrolizidine alkaloids from *Senecio paludosus* and *Senecio cordatus* dried plants by MAE with methanol at 65 to 100°C for 20 to 30 min. Mattina *et al.* reported on the extraction of taxanes from *Taxus* biomass by MAE with ethanol. Using 5 g of freshly harvested needles (moisture content 55 to 65%) soaked in 5 mL of water prior to MAE and 10 mL ethanol at 85°C for 9 min resulted in about 90%

recovery. This procedure would significantly reduce the costs of the extraction of taxanes from biomass with no reduction in the extraction yields.

Multistage Countercurrent Distribution

G. Johansson, Chemical Center, Lund, Sweden

This article is reproduced from *Encyclopedia of Analytical Science*, Copyright © 1995 Academic Press.

Theory

The separation of chemical compounds by partitioning between two liquid phases, so-called liquid–liquid extraction, can be made more effective by using it as a cascade process. One way in which this can be carried out is by multiplicative partitioning, also called countercurrent distribution (CCD). This process, in which complete partition equilibrium is achieved in each step, is presented schematically in Figure 1. The principle is that two sets of liquid phases, the upper and lower phase, come into contact with each other stepwise. The bottom phases are numbered 0, 1, 2 and so on. The sample to be analysed (fractionated) is included in the first system (containing bottom phase number 0). Before each transfer of the upper phases (to the right in Figure 1) the two-phase systems are equilibrated by mixing and

the sample components are distributed between each pair of phases (each full two-phase system). The partitioning of a pure substance between the phases of a two-phase system can be expressed either by a partition coefficient, K , defined as the ratio of the concentrations (C) of the component in the phases:

$$K = \frac{C \text{ (in phase I)}}{C \text{ (in phase II)}} \quad [1]$$

or by a partition ratio, G , defined as the ratio of the masses (m) of the components in the phase:

$$G = \frac{m \text{ (in phase I)}}{m \text{ (in phase II)}} \quad [2]$$

K and G are related by eqn [3]:

$$G = K \frac{\text{Volume (phase I)}}{\text{Volume (phase II)}} \quad [3]$$

In the following the upper phase is chosen as phase I. A convenient way of analysing the CCD process is to calculate the amounts (in fractions) of a pure

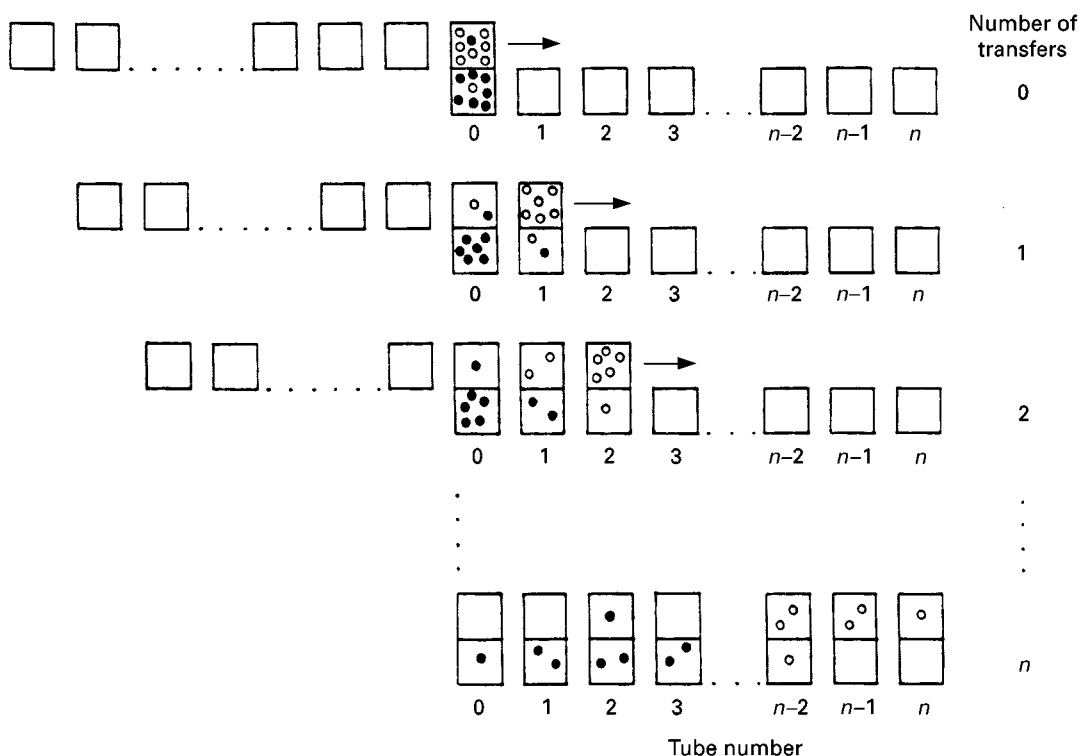

Figure 1 Principle of CCD. The upper phases are transferred stepwise from left to right. Between each transfer the two-phase systems are equilibrated by shaking and the phases are allowed to settle. Filled circle, substance with small G value; open circle, substance with large G value.

component in the various phases based on its G value. In the initial two-phase system (number 0) the component is distributed with the fractions p in the upper phase (phase I) and q in the lower phase (phase II). By definition $p + q = 1$. When the upper phase of system number 0 is combined with the pure lower phase number 1 equilibration of this system will make the transferred fraction p distribute as p/q ($= G$) giving the fraction p^2 in the upper phase and the fraction pq in the lower phase. In the new system number 0, with a new upper phase, the remaining fraction q will partition likewise and the equilibration results in the fraction pq in the upper phase and q^2 in the lower

phase. The resulting distribution after 10 transfers in the 11 tubes 0–10 is shown in **Figure 2**. In the same figure the material in each tube (upper plus lower phase) has been calculated. These values are the same as the terms obtained when $(q + p)^{10}$ is written as a polynomial. More generally, the amount of material $T_{n,i}$ (in fractions), in tube number i after a CCD with n transfers is given by eqn [4]:

$$T_{n,i} = \frac{n!}{i!(n-i)!} p^i q^{n-i} \quad [4]$$

The volume ratio is kept constant during the process. By using the relations $G^i = p^i/q^i$ and $(1 + G)^n =$

pq^{10}	$10p^2q^9$	$45p^3q^8$	$120p^4q^7$	$210p^5q^6$	$252p^6q^5$	$210p^7q^4$	$120p^8q^3$	$45p^9q^2$	$10p^{10}q$	p^{11}	Amount in upper phase
q^{11}	$10pq^{10}$	$45p^2q^9$	$120p^3q^8$	$210p^4q^7$	$252p^5q^6$	$210p^6q^5$	$120p^7q^4$	$45p^8q^3$	$10p^9q^2$	$p^{10}q$	Amount in lower phase
0	1	2	3	4	5	6	7	8	9	10	i
q^{10}	$10pq^9$	$45p^2q^8$	$120p^3q^7$	$210p^4q^6$	$252p^5q^5$	$210p^6q^4$	$120p^7q^3$	$45p^8q^2$	$10p^9q$	p^{10}	Amount in each tube

Figure 2 Distribution of a component which partitions in the ratio p/q between the upper and lower phase—after a CCD with 10 transfers. The amounts are given in fractions, i.e. $p + q = 1$.

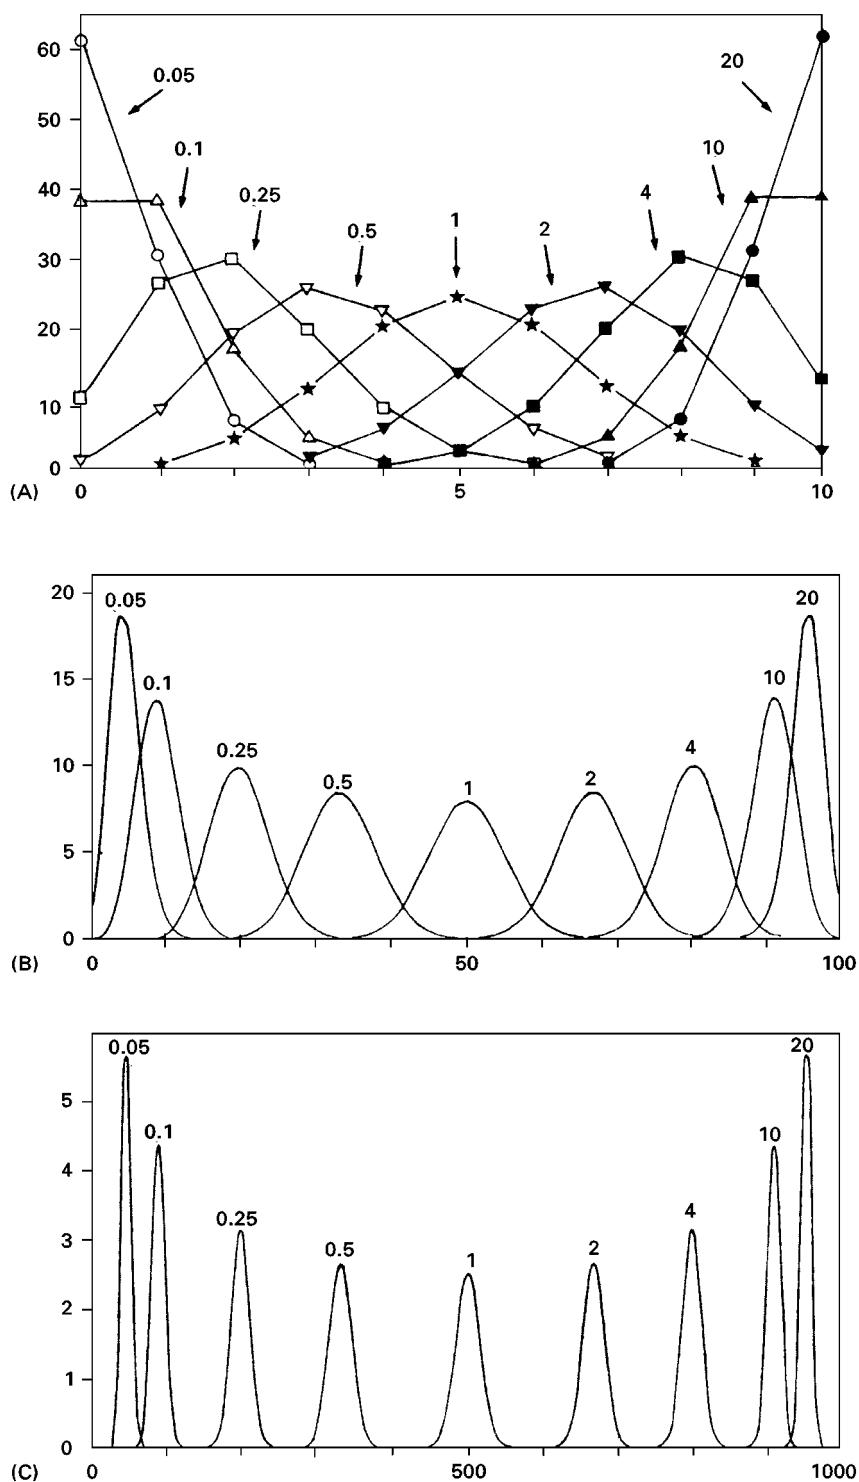

Figure 3 The resulting CCD profiles after (A) 10 transfers, (B) 100 transfers and (C) 1000 transfers for substances with the indicated G values.

$(1/q)^n$, eqn [5] is obtained:

$$T_{n,i} = \frac{n!}{i!(n-i)!} \frac{G^i}{(1+G)^n} \quad [5]$$

This relationship has been used to calculate the distribution profiles in Figure 3 for three cases: i.e. with the number of transfers (n) equal to 10, 100 and 1000. In each case the distributions of components with

G values of 0.05, 0.1, 0.25, 0.5, 1, 2, 4, 10 and 20 are shown. The resolution of components with various G values increases with the increase in the number of transfers. This is due to the fact that the difference in the position (tube number) of the peaks (with given G values) is proportional to the number of transfers, while the peak width only increases with the square root of the number of transfers.

The width of a peak Δr , covering 99.7% of the compound, can be approximately calculated using eqn [6]:

$$\Delta r = \frac{6\sqrt{nG}}{(1 + G)} \quad [6]$$

The relative width of a peak, $\Delta r_{\text{rel}} = \Delta r/n$, is given in Table 1 for $G = 1$ and a number of n values.

The most effective separation of two components, with partition coefficients K_1 and K_2 , is achieved when their distribution peaks are oriented symmetrically around the middle of the tube train, i.e. tube $i = n/2$. This, as can be seen in Figure 3, is equal to the relation $G_1 = 1/G_2$ which can be written as $G_1 \times G_2 = 1$. By combining this relation with eqn [3] the volume ratio, V , to be used for optimal separation can be calculated as shown in eqn [7]:

$$V = \frac{1}{\sqrt{K_1 K_2}} \quad [7]$$

The ratio between the K values of two substances 1 and 2 is called the separation factor, β , and is a measure of the separability of the substances. In Table 2 the number of transfers necessary for virtually complete (more than 99.5%) separation has been calculated for various β values.

The G value of a component which has its maximum peak value in tube number \hat{i} after n transfers is given by the approximate eqn [8]:

$$G = \hat{i}/(n - \hat{i}) \quad [8]$$

Table 1 The absolute, Δr , and relative, Δr_{rel} , peak width (percentage of the total number of tubes) of a substance with $G = 1$ after a CCD with n transfers

n	Δr (no. of tubes)	Δr_{rel} (%)
20	13	67
50	21	42
100	30	30
200	42	21
500	67	13
1000	95	9.5
2000	134	6.7
5000	212	4.2

Table 2 Number of transfers, n , in a CCD necessary to separate two substances, 1 and 2, with a given separation factor $\beta = K_1/K_2$. The volume ratio is chosen in such a way (eqn [7]) that $G_1 \times G_2 = 1$

β	G_1	G_2	n
2	0.709	1.414	264
3	0.577	1.732	110
4	0.500	2.00	70
9	0.333	3.00	30
16	0.250	4.00	20
25	0.200	5.00	16
36	0.167	6.00	14
49	0.143	7.00	12
81	0.111	9.00	10
400	0.050	20.0	6
2500	0.020	50.0	4

The G value can also be obtained by comparing the amount of a substance in two consecutive tubes, numbers i and $i + 1$. By combining the expressions for $T_{n,i}$ and $T_{n,i+1}$ obtained from eqn [5] the G value is obtained as in eqn [9]:

$$G = \frac{T_{n,i+1}}{T_{n,i}} \frac{i+1}{n-i} \quad [9]$$

By following the apparent G values over a distribution peak the presence of several substances differing slightly in their G values can be detected.

Various Modes of Multiplicative Partitioning

The basic process of CCD has been described, but it can be varied in a number of ways.

Single Withdrawal Procedure

In this process the addition of fresh upper phases is not stopped after n transfers, but continues from the left while the overflowing upper phases (to the right) are collected. This process is therefore similar to a chromatographic system with the lower phases corresponding to the stationary phase of the column and the upper phases corresponding to the elution liquid. Substances with high G values are easily eluted in this way while those with low G values need a great number of steps to be carried through the CCD train. The greater the number of transfers the more diluted the substance will be when leaving with the overflowing upper phases. Likewise the upper phases can be chosen as the stationary phase and the lower phases can be used as the eluting phases. In this case substances with low G values rapidly eluted.

O'Keefe Partitioning

The multiplicative partitioning can be carried in such a way that a new portion of the solute mixture to be separated is added after each transfer step. This method of carrying out the partitioning is called O'Keefe partitioning. Several two-phase systems are arranged in a row and a solute sample is included in the centre system. After equilibration and settling all the upper phases are moved one step to the right and the overflowing upper phase is collected. Then all the lower phases are moved one step to the left and the one to the extreme left is collected. The remaining set is completed with one fresh lower phase (to the right) and one fresh upper phase (to the left) to restore the original number of systems. After addition of a new portion of solute to the centre system the next cycle takes place. Substances with $G > 1$ will be recovered in the upper phases collected to the right and substances with $G < 1$ in the lower phases removed to the left. This process is used when large amounts of substances are to be separated. The number of systems is usually small, e.g. 7, 9 or 11.

A similar process, called Watanabe–Morikawa partitioning, differs in that the ongoing addition of solute mixture is done in the first system of the row. This is useful when only components with high or low G values are to be isolated.

Description of Some CCD Apparatus

CCD with only a few transfers (up to 10) can easily be carried out by using a set of separating funnels for mixing, settling and phase separation. For small phase volumes, 0.5–5 mL, the separating funnels can be replaced by test tubes and the upper phases can be transferred with the aid of a pipette. For CCDs with more than 10 transfers it is strongly advised that some kind of automatic apparatus is used. Some examples of such apparatuses are presented next.

All-Glass CCD According to Craig

Several glass units, allowing mixing, settling and phase transfers (Figure 4) are arranged in batteries on a horizontal axis. Movement about this axis can be used to gently mix the phases, to put the glass units in position for settling of the phases and for decanting the upper phases, respectively. The times for each part of the CCD cycle as well as the number of transfers can be programmed. Standard types of such machines allow 50 transfers while more advanced machines may be used for up to 1000 transfers. The glass units can be obtained in various sizes but standard tubes have space for *c.* 2 mL (fixed amount) of lower phase and up to 5 mL of upper phase.

Figure 4 Section of the all-glass apparatus for CCD constructed by Craig. (A) Two segments (or tubes) are shown from side and top views. Normally 50–1000 tubes are connected and placed on a horizontal rack which allows simultaneous mixing of all tubes. (B) By turning the axis the upper phases can be decanted. When returning to the original position the upper phases are transferred to the neighbouring tube.

Thin-Layer CCD According to Albertsson

This CCD apparatus is designed to be used with aqueous two-phase systems which normally need a long time for settling. By using systems with low heights, only a few millimetres, the settling time will be acceptable (5–20 min). The operating unit (Figure 5) consists of two circular plates of polyacrylic plastic, one on top of each other: the lower plate (stator) is fixed while the upper one (rotor) can be rotated stepwise. Both plates have 60 (or 120) radially oriented cavities which pair-wise form containers for the two-phase systems. The cavities of the stator contain the lower phases (normally 0.8 mL) while the upper phases (0.2–2 mL) are situated in the

Figure 5 Thin-layer CCD apparatus according to Albertsson. (A) The two discs of polyacrylic plastic contain matching cavities for the upper and lower phases and by rotation the upper plate can move all upper phases relative to the lower ones. See text for further details. (Adapted from Albertsson P-Å (1986) *Partition of Cell Particles and Macromolecules*, 3rd edn, p. 126. New York: Wiley (interscience), by permission.) (B) A thin-layer CCD machine constructed by Albertsson.

cavities of the rotor and therefore can be transferred relative to the lower phases by rotating the upper plate. The two plates are placed on the shaking table of a machine which also contains a drive for the upper plate rotation. The phase systems are added to each container (chamber) via openings in the upper side of the rotor. These openings, during the run, are covered with a ring-formed lid. The shaking and settling periods and number of transfers are controlled by an automatic unit. After the CCD run is completed the two-phase systems can be collected by use of a fraction collector. This is a circular rack with the same number of test tubes (4 mL) as chambers. The rack is placed over the inlet holes and is inverted together with the plates which are then emptied.

Centrifugal CCD According to Åkerlund

This kind of CCD machine uses centrifugation to speed up the settling of the phases. It consists of an outer ring with cavities for the lower phases (attached to a bottom plate) and an inner plate with cavities for the upper phases (Figure 6.) The inner plate can rotate relative to the outer ring. When the chambers have been loaded with systems they are covered with a lid. As in the case of the thin-layer machine the functional unit is placed on a (round) table which can be shaken. In this case, however, the table can also rotate to allow centrifugation of the mixed systems which speeds up the settling of the phases. The upper phases are then transferred to the neighbouring lower

Figure 6 Centrifugal CCD according to Åkerlund. A section of the circular separation unit is shown. It is composed of four units: c, the outer ring with cavities for the lower phase; d, the inner plate with cavities for the upper phase; e, the lid; and f, an O-ring for sealing. The position of the two-phase system during centrifugation is shown, with the upper phase, a, and the lower phase, b. (From Johansson G, Åkerlund H-E and Olde B (1984) *Journal of Chromatography* 311: 277, by permission.)

phases by rotation of the inner plate when the whole system is still spinning and the phases are in a vertical position. After the transfer the centrifugation is stopped and a new cycle begins with the shaking process. After the run the phases are collected by pipette.

Continuous apparatus, such as extraction columns and coil planet centrifuges, also corresponds to a CCD process but differs in that no discrete steps are used and equilibrium is not reached.

Analytical Applications

Many metal ions can be separated by using various kinds of water/organic solvent systems for counter-current distribution. Metal chelators, such as dithizone, 8-quinolinol, cupferron, dimethylglyoxime and acetylacetone, are used specifically to extract metal ions into the organic phase. Likewise certain anions such as halides, thiocyanate or nitrate can be used. For example, uranium and plutonium have been separated by using an aqueous phase containing 8 mol L^{-1} nitric acid.

Biochemical Applications

CCD has been used for fractionation of a number of biochemical substances and cellular particles as well as cells and viruses. Peptides, proteins and nucleic acids have been fractionated by using aqueous two-phase systems composed of water and the two polymers dextran and poly(ethylene glycol) (PEG). The partition coefficients of the solutes can be adjusted by addition of various salts to the two-phase system and

by adjusting the pH value. More selective adjustment of the partitioning has been carried out by linking an affinity ligand to one of the phase-forming polymers which then is concentrated in one of the phases.

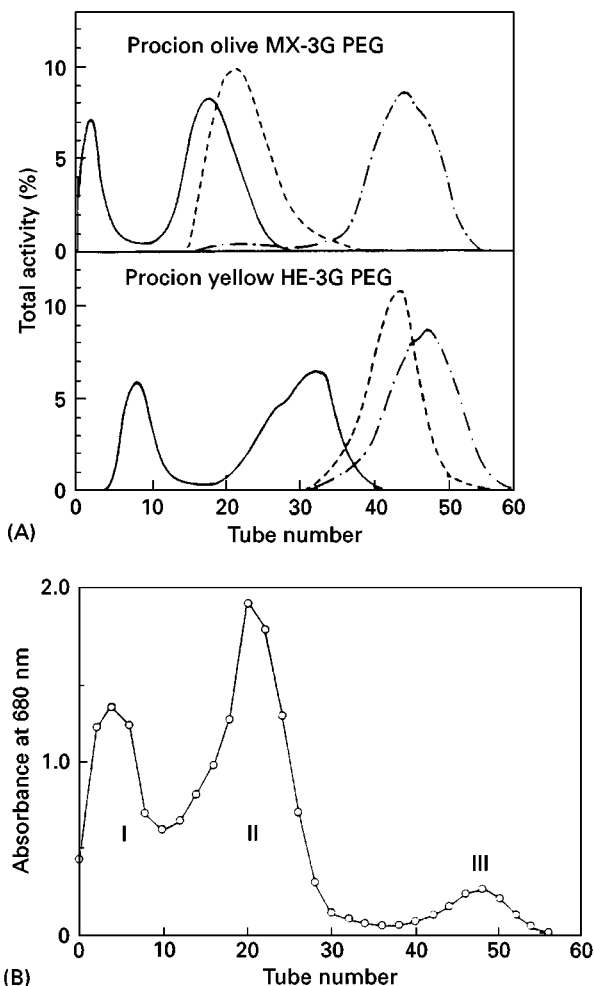

Figure 7 Countercurrent distribution of proteins and cell organelles. (A) Distribution of the enzymes hexokinase (—), 3-phosphoglyceratekinase (---), and phosphofructokinase (·····) when an extract of baker's yeast was applied to a CCD with 55 transfers. The textile dyes Procion olive MX-3G or Procion yellow HE-3G were used as PEG-bound affinity ligands enriched in the mobile upper phase. Composition of two-phase system: 88% (w/w) water, 7% (w/w) dextran 500, 5% PEG with $M_r = 8000$, including dye-PEG, 1% of total PEG 50 mmol L^{-1} sodium phosphate buffer, pH 7.0, 0.2 mmol L^{-1} ethylenediamine-tetraacetic acid and 5 mmol L^{-1} 2-mercaptoethanol. Volume ratio, 1.5. Temperature, 3°C . A centrifugal CCD apparatus was used with 5 min shaking and 3 min settling (centrifugation). (Adapted from Johansson G, Joelsson M and Åkerlund H-E (1984) *Journal of Chromatography* 298: 483, by permission.) (B) Fractionation of photosynthetic particles, chloroplasts, from spinach using a thin-layer CCD apparatus with 56 transfers and a dextran-PEG two-phase system. Peak I, intact chloroplasts surrounded by their envelope; peak II, naked thylakoid membranes (class II chloroplasts); peak III, chloroplasts surrounded by a 'bag' of plasma membrane also containing cytoplasm, mitochondria and peroxisomes. (From Larsson C, Collin C and Albertsson P-Å (1971) *Biochimica Biophysica Acta* 245: 425, by permission.)

Biological membranes, cell organelles, whole cells and viruses can be fractionated by CCD in the same kind of systems. In this case, however, the particles partition between the two liquid phases and the interface between them. The CCD is therefore usually carried out using a stationary interface. This is achieved by using a smaller volume of the lower phase than is needed to fill the lower cavities. Therefore, a portion of the upper phases will also be stationary. The *G* value satisfying eqn [5] is in this case defined as the amount of a pure compound, at equilibrium, in the mobile part of the upper phase divided by the amount of the compound in the rest of the system (stationary upper phase, interface and lower phase). Examples of CCD of proteins and of chloroplasts, the photosynthetic organelle in green plant cells, are given in Figure 7.

Solid-Phase Extraction

C. F. Poole, Wayne State University, Detroit, MI, USA

Copyright © 2000 Academic Press

Solid-phase extraction is a method used to isolate analytes from a gas, fluid or liquid by their transfer to and retention on a solid-phase sorbent. After separation of the sorbent from the sample the analytes are recovered by elution using a liquid or fluid, or by thermal desorption into the gas phase. If the analytes are recovered from the sorbent in a final volume that is only a fraction of the sample volume, then concentration as well as isolation is achieved. In addition, if the sorption step, any subsequent rinse steps, and the elution conditions are selective for retention and recovery of the analyte, then matrix simplification is achieved. Isolation, concentration and matrix simplification are the primary goals of solid-phase extraction.

Probably the earliest application of solid-phase extraction was the use of charcoal-filled columns in the 1950s to isolate organic contaminants from surface waters for toxicity evaluation. The large volume of water generally sampled (more than 1000 L over several days) precluded the use of liquid-liquid extraction techniques. The subsequent evolution of solid-phase extraction techniques is summarized in Figure 1.

The introduction of macroporous polymers in the early 1970s was responsible for rekindling interest in solid-phase extraction and extending its scope to air sampling and the isolation of drugs from

biological fluids. These sorbents had reasonable mechanical strength compared with gels, a large surface area and sample capacity, low water retention, and gave high sample recoveries by solvent desorption. Compared with carbon the overall analyte recovery was generally better and irreversible adsorption and catalytic activity greatly diminished. These

Figure 1 Time line showing the general evolution of solid-phase extraction techniques.

Figure 2 Schematic diagram showing the typical construction of a solid-phase extraction cartridge and a vacuum manifold for parallel sample processing.

properties, together with a reduction in the amount of material needed for identification due to improved instrumentation, resulted in the general use of small columns, similar in size to those in use today. Porous polymers with high thermal stability and low water retention revolutionized the room temperature sorbent extraction of volatile organic compounds from air or purge gas from water samples. Trapped compounds were thermally desorbed directly into a gas chromatograph for analysis. Automated systems based on the above process are used for routine analysis today.

Solid-phase extraction for liquid samples became a widely used laboratory technique with the introduction of disposable sorbent cartridges containing porous, siloxane-bonded silica particles, sized to allow sample processing by gentle suction (Figure 2). A typical solid-phase extraction cartridge consists of a short column (generally an open syringe barrel) containing a sorbent with a nominal particle size of 50–60 µm, packed between porous metal or plastic frits. A large number of sorbents are in use today corresponding to the desire for general purpose, class-specific and even compound-specific extractions.

Slow sample processing rates for large sample volumes, low tolerance to blockage by particles and sorbed matrix components, and problems arising from the low and variable packing density of cartridge devices spawned the development of alternative sampling formats based on disc technology. At least three different designs for solid-phase extraction discs are offered commercially today. The particle-loaded membranes consist of a web of polytetrafluoroethylene (PTFE) microfibrils, suspended in which are sorbent particles of about 8–10 µm diameter. The membranes are flexible with a homogene-

ous structure containing 80% (w/w) or more of sorbent particles formed into circular discs 0.5 mm thick with diameters from 4 to 96 mm. For general use they are supported on a sintered glass disc (or other support) in a standard filtration apparatus using suction to generate the desired flow through the membrane (Figure 3). Particle-embedded glass fibre discs contain 10–30-µm sorbent particles woven into a glass fibre matrix. The small diameter discs are rigid and self-supporting, while the larger diameter discs require a supporting structure. Speediscs® (Figure 4) consist of a sandwich of 10-µm sorbent particles held between two glass-fibre filters, with a screen to hold the filters in place. Disc technology has contributed directly to the automation of solid-phase extraction through the development of the multiwell extraction plate (Figure 5), which is used for the clean-up of samples in high-throughput screening techniques for drug development. Direct coupling of solid-phase extraction and high pressure liquid chromatography for on-line sample processing and analysis is now routine and the direct coupling of solid-phase extraction and gas chromatography for the analysis of liquid samples has moved beyond the research phase. Several research groups have demonstrated the direct coupling of solid-phase extraction and electrophoretic and thin-layer chromatographic separation techniques.

Replacement for Liquid–Liquid Extraction

Solid-phase extraction was introduced as a replacement for liquid–liquid extraction to give a practical and economic solution to the real and perceived problems associated with solvent extraction techniques. Liquid–liquid extractions are labour

Figure 3 Typical cartridge and vacuum filtration formats for solid-phase extraction using discs.

intensive, difficult to automate, and frequently plagued by practical problems, such as emulsion formation. Liquid-liquid extractions also tend to consume large volumes of high purity solvents, which may have significant health hazards and disposal costs associated with their use. In contrast, solid-phase extraction benefits from lower intrinsic costs, reduced processing times, low solvent consumption and simpler processing procedures. Solid-phase extraction procedures are easily automated using robotics, or special purpose flow processing units that

simultaneously extract samples and prepare them for automatic injection, or by using centrifugal analysers, which can batchwise process multiple samples. Solid-phase extraction is convenient for field sampling since it minimizes the transport and storage problems of bulk samples, which have to be returned to the laboratory for processing.

Solid-phase extraction techniques have their own, although different, problems to those of liquid-liquid

Figure 4 Exploded-view of the Speedisc® used for solid-phase extraction.

extraction. The sorption properties of manufactured sorbents are not as reproducible as solvent properties. Basic drugs, for example, are often retained on silica-based, chemically bonded sorbents by a mixed retention mechanism involving non-specific sorption by the bonded phase and ion exchange interactions with accessible, dissociated silanol groups. The mixed retention mechanism can interfere in the recovery of analytes since solvent elution may be ineffective for removing ionically bound analytes, and the extent of binding through ionic sites can vary for different sorbent lots. Sorbents tend to have a higher level of contamination by manufacturing and packaging materials than do solvents. The chemical background from impurities may interfere in the subsequent analysis of the sample. Solvent rinsing of cartridges and discs and the running of blanks to establish background contamination levels diminishes sample throughput and adds significantly to solvent consumption and processing costs. Sample processing problems, such as column overloading, displacement and blocking of sorbent pores, easily go unnoticed, resulting in changes in analyte recovery. Sample overload and displacement are more important for extraction based on adsorption than for extraction based on absorption.

When choosing between liquid-liquid or solid-phase extraction for a particular problem, economic, as well as technical features, should be taken into consideration. In this sense, liquid-liquid and solid-phase extraction techniques should be considered complementary approaches, and although the general trend is towards the replacement of liquid-liquid extraction methods by solid-phase extraction, this is never likely to be a complete replacement.

Disc Versus Cartridge Format

Cartridges have a small cross-sectional area, a slow sample processing rate, and a low tolerance to blockage by particles and adsorbed matrix components. For large sample volumes containing suspended particles, discs are likely to function better. Discs provide shorter sample processing times due to their larger cross-sectional area and decreased pressure drop, enabling higher sample flow rates to be used. The larger cross-sectional area also reduces problems with plugging. For example with a high particle burden, discs with integral or separate depth filters are available, as well as different materials that can be added to the surface of the disc as filter aids.

Because of the low packing density of typical cartridge devices, longer sorbent beds than are needed for extraction are used to compensate for reduced retention resulting from channelling. Increased bed

mass results in increased non-specific matrix adsorption and dirtier extracts. The use of smaller particles and the greater mechanical stability of discs reduces channelling, and the optimized use of bed mass results in a cleaner background and lower interferences due to reduced matrix adsorption. For small sample sizes it is easier to miniaturize discs than cartridges, and several disc devices (e.g. microdiscs, pipette tips, etc.) that contain only a few milligrams of sorbent for processing small samples are available. Immobilized analytes on microdiscs facilitate integrated sample processing techniques such as in-vial extraction and on-disc derivatization.

Inorganic Oxide Adsorbents and their Applications

The most important adsorbents for extraction and matrix simplification are silica gel, alumina, Florisil and diatomaceous earths. Silica gel, prepared from sodium silicate using the sol-gel procedure, is the most widely used general-purpose adsorbent. Silica gels used for solid-phase extraction have surface areas of about $300\text{--}800\text{ m}^2\text{ g}^{-1}$, pore sizes from 4–10 nm, and an apparent pH of 5.5–7.5. The apparent sorbent pH is characterized as the observed pH of a 5% (w/w) aqueous suspension. Alumina is prepared by the low temperature dehydration ($< 700^\circ\text{C}$) of alumina trihydrate and is a mixture of γ -alumina with small amounts of α -alumina (less active form) and sodium carbonate. Depending on processing conditions, alumina is available as neutral ($\text{pH } 7.5 \pm 0.5$), weakly acidic ($\text{pH } 6.0 \pm 0.5$), acidic ($\text{pH } 4.5 \pm 0.5$) and basic ($\text{pH } 9.5 \pm 0.5$) forms. Adsorbents used for extraction and matrix simplification have a surface area of about $150\text{ m}^2\text{ g}^{-1}$ and a pore size of 6 nm. Florisil is a magnesium silicate prepared by precipitation from a mixture of magnesium sulfate and sodium silicate solutions followed by calcining at about 1200°C . It has a surface area of about $250\text{--}300\text{ m}^2\text{ g}^{-1}$ and an apparent pH of about 8.5. Diatomaceous earths are flux-calcined forms of natural silica with very small surface areas. They are used as a filter aid and as a dispersant for liquid extraction using matrix dispersion techniques (see matrix dispersion).

The general extraction mechanism and applications of the inorganic oxide adsorbents are summarized in Table 1. Adsorbent properties that increase retention are a larger surface area and a high activity. Adsorbent activity is controlled by the intentional addition of water to the dried adsorbent prior to use and by drying extracts with anhydrous sodium sulfate, or a similar drying agent, prior to applying the extract to the adsorbent. A small column of

Table 1 General applications of solid-phase extraction**(1) Inorganic oxide adsorbents**

- Isolation of low and medium polarity analytes from non-aqueous solutions
- Isolation of cations (alumina and silica) and anions (alumina) from buffered aqueous solutions
- Matrix simplification by fractionation into groups containing a similar number and type of functional group

Examples

- ⇒ Isolation of organochlorine pesticides and polychlorinated biphenyls from transformer oil, animal fats and oils, etc. using Florisil.
- ⇒ Isolation of lipids by chromatography over silica gel using chloroform to elute simple lipids, acetone to elute glycolipids and methanol to elute phospholipids.
- ⇒ Group fractionation of polycyclic aromatic compounds (hydrocarbons, *N*-containing and *OH*-containing) in synthetic fuels over alumina using a step solvent gradient.
- ⇒ Isolation of paraquat and diquat from high moisture crops in a pH 9 aqueous extract using silica gel
- ⇒ Mycotoxins in feeds using silica gel
- ⇒ Pesticides in foods, feeds and soil extracts; alkaloids, pigments and flavour compounds from plants; sugars and caffeine in cola beverages, inorganic anions and organic acids in aqueous solution using alumina; steroids and vitamins from creams and oil-based suspensions.

(2) Low specificity sorbents (aqueous solutions)

- Isolation of neutral and ionizable analytes from aqueous solution. Weak acids and bases by ion suppression. Strong acids and bases using ion pair extraction (alternative to ion exchange)
- Retention increases with solute size and is reduced by polar interactions (particularly hydrogen-bonding) and ionization
- Polar bonded phases provide only weak retention and are not particularly useful unless elution of the analyte is a problem from non-polar sorbents

Examples

- ⇒ Isolation of agricultural and industrial chemicals from surface waters using C₁₈, carbon or poly(styrene-divinylbenzene) (PS-DVB)
- ⇒ Isolation of drugs from biofluids using C₁₈, C₈, PS-DVB or cyanopropyl (CN)
- ⇒ Isolation of macromolecules from biofluids and fermentation broth using C₄
- ⇒ Isolation of pigments and colouring materials from beverages and food extracts using C₁₈
- ⇒ Isolation of carbohydrates and nucleosides from biofluids using AMINO
- ⇒ Isolation of proteins, peptides and surfactants using DIOL

(3) Low specificity sorbents (organic solvents)

- Retention depends on the type and number of functional groups. Solute size is not important
- CN Strong dipole-type interactions and weak hydrogen-bond acidity
- AMINO Strong hydrogen-bond base and weak hydrogen-bond acid. Weak dipole interactions
- DIOL Strong hydrogen-bond acid and weak hydrogen-bond base with significant capacity for dipole-type interactions

Examples

- ⇒ Isolation of polar pesticides from fats and oils
- ⇒ Isolation of polycyclic aromatic compounds from fuel oils
- ⇒ Active ingredients from ointments and suppositories

(4) Ion-exchange sorbents

- In general strong ion exchangers are used to isolate weak acid/bases of opposite charge and weak ion exchangers strong acid/bases
- Retention selectivity can be adjusted by manipulating the sample pH and ionic strength
- Choice of competing ion, its concentration and eluent pH controls selectivity for matrix simplification and elution
- Isolation of macromolecules in an active form may require special non-denaturing sorbents based on cellulose, agarose or dextran

Examples

- ⇒ Isolation of carboxylic, sulfonic and phosphoric acids, phenols, amines and inorganic ions from water
- ⇒ Isolation of amino acids, organic acids, nucleosides and nucleotides from biofluids
- ⇒ Isolation of organic acids and bases from coal-derived and synthetic fuels
- ⇒ Isolation of organic acids, phenols and amines from wine, fruit juices and food extracts

sodium sulfate connected in tandem with the adsorbent cartridge can be used as an additional precaution. The Brockmann scale (based on the relative retention of test dyes, see Table 2) provides a widely used standardized scale of adsorbent activity. Adsorbents of defined activity are prepared by adding a known amount of water to the adsorbent, shaking to avoid clumping, and then allowing the adsorbent to equilibrate overnight in a closed container. Analyte properties that increase retention depend on the num-

ber and type of functional groups present. Hydrogen-bonding functional groups are strongly retained, those with a significant dipole-character are retained to a lesser extent, and polarizable functional groups are the least retained. Irreversible adsorption and catalytic degradation of sensitive analytes can occur on all inorganic oxide adsorbents and is a source of low recovery for some analytes. Alumina and silica can function as selective ion exchange sorbents with buffered aqueous samples (see Table 1).

Table 2 Standardization of adsorbent activity

Brockmann activity grade	Percentage of water (w/w)		
	Alumina	Silica gel	Florisil
I ¹	0	0	0
II	3	5	7
III	6	15	15
IV	10	25	25
V	15	38	35

¹Activate sorbents by heating alumina at 400°C for 8–12 h, silica gel at 180°C for 8–12 h, and Florisil at 130°C for 8–12 h.

Coating silica or alumina with chemical reagents, such as sulfuric acid, sodium hydroxide, alkaline potassium permanganate, silver nitrate, etc., is used to improve the selectivity of the isolation of some analytes from their matrix. Silver nitrate, for example, improves the isolation of olefins from hydrocarbons due to formation of charge-transfer complexes. Acids can be used for the selective isolation of bases and vice versa. Silica impregnated with 2,4-dinitrophenylhydrazine is widely used for the selective isolation of volatile ketones and aldehydes from air for analysis by high pressure liquid chromatography.

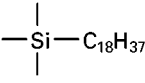

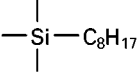

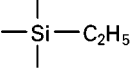

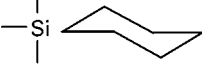

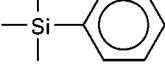

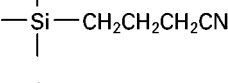

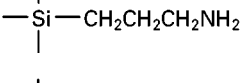

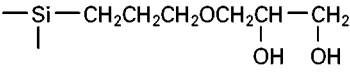

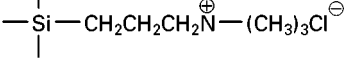

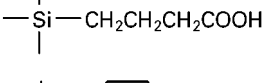

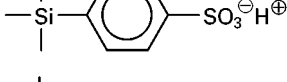

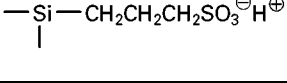

Low Specificity Sorbents and Their Applications

Low specificity sorbents include silica-based, chemically bonded sorbents, macroreticular porous polymers and various forms of carbon. Silica-based, chemically bonded sorbents are derived from materials developed for high pressure liquid chromatography. They are generally prepared by reaction of monofunctional or trifunctional silanes with silica gel followed by end-capping in some cases. Trifunctional reagents result in sorbents with a polymeric-bonded layer of higher carbon loading and greater acid stability and are the more common type of sorbent in general use. Chemically bonded sorbents can be prepared with a wide range of bonding densities, pore sizes and functional group types. Some common examples are given in Table 3. Chemically bonded sorbents with large surface areas, long alkyl chains and high phase loading maximize retention of small analytes from aqueous solution, while wide-pore materials with low phase loading and short alkyl chains are generally used to isolate macromolecules. Chemically bonded sorbents with immobilized polar functional groups are used to isolate analytes from organic solutions, based on their selective interactions with analyte polar functional groups (see Table 1).

The macroreticular porous polymers are copolymers of styrene-divinylbenzene or acrylic esters, prepared by suspension polymerization to yield particles consisting of agglomerates of randomly packed microspheres permeated by a network of holes and channels (Table 4). They are used exclusively for extraction from aqueous solution and are more retentive than most chemically bonded phases. They possess a high sample capacity and are frequently used in large-scale isolation studies and for the purification of industrial products. Tenax[®], a polymer based on 2,6-diphenyl-4-phenylene oxide, revolutionized the sorbent trapping of volatile organic compounds from air and the purge-and-trap analysis of volatile organic compounds in water. It exhibits strong retention of semivolatile organic compounds (>C₇) at room temperature with little adsorption of water vapour and can be rapidly heated to high temperatures, without thermal breakdown, for the recovery of analytes by thermal desorption. Since no single adsorbent is ideal for trapping all analytes it is common practice to use cartridges packed with several adsorbent beds in series, so that a broad range of compounds with different molecular weight and polarity can be trapped on a single cartridge. Besides Tenax, different forms of carbon, silica gel and liquid-coated sorbents are used. In a multiple bed cartridge, each bed protects the next, increasingly active bed, by preventing compounds from being held so strongly that they cannot be desorbed quickly without decomposition. During thermal desorption the carrier gas passes through the trap in the reverse direction to the sample flow and the desorbed compounds are swept onto the separation column in a gas chromatograph. A cryogenic interface may be used to refocus the desorbed sample to improve the chromatographic separation. The complete processes of desorption and separation can be automated for sample cartridges stored in an autosampler.

The common forms of carbon used in solid-phase extraction are granular activated carbon, graphitized carbon blacks and carbon molecular sieves. Granular activated carbons are prepared by the low temperature oxidation of vegetable charcoals. They have large surface areas (300–2000 m² g⁻¹), a wide pore size distribution, and a heterogeneous surface containing active functional groups. Their use in solid-phase extraction is largely confined to the isolation of dissolved organic compounds in surface waters, and as the sorbent material in personal monitors for sampling workplace atmospheres. The most common form of personal monitor makes use of a sorbent cartridge filled with activated charcoal in conjunction with a small pump to maintain a fixed flow of air through the cartridge. Trapped volatile compounds

Table 3 Structures of silica-based chemically bonded sorbents

Type	Functional group	Structure
C ₁₈	Octadecyl	
C ₈	Octyl	
C ₂	Ethyl	
CH	Cyclohexyl

CN	Cyanopropyl	
NH ₂	Aminopropyl	
DIOL	2,3-Dihydroxypropoxypropyl	
SAX	Trimethylaminopropyl (quaternary amine)	
CBA	Carboxypropyl	
SCX	Benzenesulfonic acid	
PRS	Propylsulfonic acid	

are then eluted with carbon disulfide or another solvent, or can be thermally desorbed by microwave heating, for separation by gas chromatography. Poor reproducibility of activated carbons and their variable chemical and catalytic activity result in limited laboratory use. Graphitized carbon blacks are more refined and generally nonporous, with surface areas between about 5–100 m² g⁻¹. They are used primarily for the room temperature trapping of volatile organic compounds (>C₄), either separately or in combination with Tenax®. Carbon molecular sieves have small pores and large surface areas (> 500 m² g⁻¹

with some >1200 m² g⁻¹). They are used primarily for the room temperature trapping of volatile organic compounds (C₁ and C₂), usually as a component of a multiple-bed sorbent trap for air sampling and purge-and-trap analysis.

Foamed polyurethanes, composed of agglomerated spherical micrometer-sized particles bonded to one another in a rigid and highly permeable structure, are suitable for sampling semivolatile organic compounds (e.g. airborne pesticides and polychlorinated biphenyls) at high flow rates. They are frequently used in conjunction with high-volume air samplers on

account of their low pressure drop compared with standard sorbent cartridges. They are used less frequently for water analysis where macroreticular porous polymers are considered a better choice.

Compound and Class-specific Sorbents and their Applications

Various forms of selective sorbents for solid-phase extraction based on ion exchange, bioaffinity, molecular recognition, and restricted access are used to supplement the general class of sorbents discussed above. Ion exchange is used to isolate ionizable compounds (usually) in aqueous solution with sorbents containing fixed ionic sites of opposite charge to the analytes of interest. Ion-exchange sorbents are usually classified as weak or strong depending on the identity of the ionic group and whether its charge is independent of the sample pH (strong ion exchanger) or can be manipulated by changing the pH (weak ion exchanger). Some examples of typical silica-based ion-exchange sorbents are indicated in Table 3. Ion-exchange sorbents with a porous polymer backbone are also commonly used and have a higher exchange capacity and a wider pH-operating range than silica-based sorbents. For many applications either silica-based or porous polymer ion-exchange sorbents with the same immobilized ionic groups can be used interchangeably, although, because of non-specific adsorption of matrix components, the chemical background of the extracts might be different. Ion-exchange sorbents are particularly attractive for the isolation of ionizable substances since the neutral molecules, which may interfere in the final chromatographic analysis, are easily rinsed from the sorbent without affecting the recovery of the ionized components. Mixed-mode sorbents containing ion-exchange sites and alkyl groups co-bonded to silica in either cartridge or disc format are popular in clinical and pharmaceutical laboratories, where they are used for the isolation of ionized drugs and their metabolites from biological fluids. Standard protocols using

mixed-mode sorbents have been developed for the isolation of most drugs of abuse (e.g. amphetamines, barbiturates, cocaine, opiates, etc.). The strong retention and the use of efficient rinse solvents results in cleaner extracts compared with single-mode sorbents, suitable for screening by thin-layer chromatography and confirmation by gas chromatography-mass spectrometry.

Resin-bound phenylboronic acids are used for the isolation of compounds with vicinal diol groups such as steroids, catecholamines and nucleotides. Surface-bonded macrocyclic ligands, cryptands, can be used for the selective isolation of metal ions. The cryptands can be synthesized with a variety of cavity sizes suitable for the isolation of different metal ions. The metal ion is sorbed in the cavity of the cryptand until released by elution with a solution of a complexing agent with a high binding constant for the metal.

Immunosorbents have been used for a long time for sample pretreatment in medicine and biology, but more general applications, such as to environmental analysis, are relatively recent. In part, this is due to the difficulty of making antibodies selective to small molecules, as well as a lack of familiarity among analytical chemists of the procedures used to make specific antibodies. Immunosorbents are prepared by covalently bonding a suitable antibody to an appropriate sorbent. A high degree of molecular selectivity is obtained based on the specificity of the antibody-antigen (analyte) interaction. Because specificity is high, immunosorbents are able to isolate target analytes from complex matrices in a single step with minimal co-extraction of matrix interferences. By taking advantage of cross-reactivity, class-specific immunosorbents for the isolation of mycotoxins, phenylurea herbicides and polycyclic aromatic hydrocarbons have been developed. Manufactured immunosorbents have been available for only a short time and the range of products is still narrow. A laboratory familiar with the techniques for raising and isolating antibodies is required.

Molecular imprinting is a technique used for preparing polymers with synthetic recognition sites

having a predetermined selectivity for a specified analyte. The imprint is obtained by arranging polymerizable functional monomers around a template (the analyte). Template–monomer complexes are formed in solution through molecular interactions and subsequently fixed in place by cross-linking. Removal of the template from the resulting polymer matrix creates vacant recognition sites that exhibit affinity for the analyte. For the time being, it is impossible to predetermine the experimental conditions for successful imprinting of target analytes. The template molecule may be difficult to leach from the imprinted polymer, reducing the binding capacity of the polymer, but more seriously, it may lead to contamination of sample extracts. Only a few practical applications using molecularly imprinted polymers for solid-phase extraction have been demonstrated so far, most of which are for the isolation of drugs from biological fluids, but the future for this technology looks very promising. Molecularly imprinted polymers should be easier and cheaper to produce in chemical laboratories than antibodies while, at least in theory, they should be capable of similar specificity.

Restricted access sorbents have been developed for the isolation of low molecular weight compounds, generally drugs, directly from biological fluids with minimum sample pretreatment. They work by preventing access of macromolecules (proteins) to those regions of the sorbent where retention of the analyte occurs. Restricted access to the retentive part of the sorbent is provided by either a physical diffusion barrier, such as a pore diameter, or by a chemical diffusion barrier, such as a polymer network at the outer surface of the particle. In addition, the outer surface of the particles must be non-adsorptive and protein-compatible. Restricted access sorbents are commonly used for automated on-line sample processing in liquid chromatography. In this case, a short precolumn packed with the restricted access material is interfaced to a separation column by a six-port switching valve. The biofluid is injected directly onto the precolumn, which retains the analytes of interest. Potentially interfering sample constituents are then flushed to waste. Macromolecules (proteins) pass through the precolumn unretained and do not interfere in the subsequent separation of the analytes. The analytes retained on the precolumn are eluted on-line to the separation column and detected. Simultaneously the precolumn is reconditioned (or exchanged) before processing the next sample. An important consideration for automated sample processing is the ability of the restricted access sorbent to repeatedly extract the analyte without change in properties or accumulation of sample matrix components.

Sample Processing Considerations

Solid-phase extraction cartridges are available in a range of sizes containing from about 35 mg to 10 g of sorbent, with the 100 mg and 500 mg sorbent cartridges (or discs) being the most widely used for extraction and the larger cartridge sizes for sample clean up. As a rough guide, the sorbed sample capacity of a solid-phase extraction device is about 1–5% of the sorbent mass. The sample volume that can be processed depends primarily on the breakthrough volume of the analyte, the concentration of the analyte matrix, sample flow rate, and the sorbent mass. The sample volume is often selected to conform to the needs of the instrumental detection step, and as instrumental methods of determination have improved in sensitivity, sample volumes have decreased in size. Regulatory authorities often indicate action levels in concentration units, which can also be used to define an adequate sample volume for analysis.

Sorbent selection is based on the considerations summarized in **Figure 6**. The sample solvent (aqueous or organic), the analyte type (non-polar, polar or ionized), and whether it is ionized (strong or weak, acid or base) provides a logical guide for method selection. Organic compounds soluble in polar organic solvents but difficult to dissolve in solvents of intermediate polarity, can be extracted in the reversed-phase mode if they can be reconstituted in aqueous solution.

Sample processing involves four distinct steps. Initially, the sorbent is conditioned with solvent to improve the reproducibility of analyte retention and to reduce the carrythrough of sorbent impurities at the elution stage. The conditioning solvent is then replaced with the same solvent as the sample solvent and the sample passed through the sampling device at a controlled flow rate. Optionally, after the sample has been processed, the sorbent is rinsed with a weak solvent to displace undesired matrix components from the sorbent without displacing the analytes. Finally, the analytes of interest are eluted from the sorbent in a small volume of strong solvent for subsequent determination. Hidden in the above description of events are a number of sub-steps that can dramatically influence analyte recovery if not adequately optimized (**Table 5**). The conditioning step is critically important for processing aqueous samples using particle-loaded membranes. The high surface tension of water combined with the microporosity of the discs results in slow and uneven flow through the discs and low analyte recovery if the discs are not first conditioned with an organic solvent. For large sample volumes, a small amount of the same organic solvent is usually added to the sample to maintain a constant

sample flow rate. The drying step between processing aqueous samples and eluting the retained analytes with a water-miscible organic solvent is also important. The purpose of the drying step is to reduce the volume of water co-eluting from the sampling device permitting further concentration of the eluent by the gas-blow down method. Drying, by suction or storage in a vacuum desiccator, should be sufficient to remove water trapped in the pores, but excessive drying can result in low analyte recovery from evaporation or inefficient elution. A new porous polymer sorbent, prepared by copolymerization of divinylbenzene and *N*-vinylpyrrolidone (Oasis HLB), and solvated by water alone, has been suggested as a solution to this problem. Recently, it was shown that all sample-processing steps are amenable to computer-aided method development, replacing the traditional experimental trial-and-error approach by fast computer simulations.

Automation

Automation provides a better utilization of laboratory resources, unattended and out-of-hours operation and improved precision compared with manual methods. Common approaches to automation differ significantly. Using robotics, samples are processed

(usually) in a similar manner to manual methods. Using flow-processing schemes, samples are extracted in parallel with computer or microprocessor control of solvent management. Sorbent conditioning, sample condition, solvent selection, rinse and elution steps are performed automatically and can be varied for method development. Positive displacement instead of suction is used for solvent control, and advanced units can be programmed to replace sorbent cartridges to increase sample throughput and inject extracts into different chromatographic instruments. On-line analysers with a direct coupling to chromatographic instruments are widely used. Solid-phase extraction using short precolumns and a switching valve interface is a routine method for analysis by liquid chromatography. Advanced systems even allow programmed replacement of the sorbent cartridges and unattended 24-hour operation. The recovery and separation steps of purge-and-trap and sorbent trapping of volatile organic compounds from air are easily automated using thermal desorption with cold trapping, if required, for the direct injection of analytes into a gas chromatograph. Major strides have been made in the on-line solid-phase extraction of water samples with solvent desorption directly into a gas chromatograph. This method is not far from becoming routine today.

Table 5 Experimental variables that influence recovery of analytes by solid-phase extraction

-
- Conditioning solvent (typically 3–5 bed volumes)
 - ⇒ Ensures reproducible retention and flow. Critical step for particle-loaded membranes
 - ⇒ Helps to minimize contamination of extracts by sorbent impurities
 - ⇒ Replace by sample solvent before processing sample
 - Flow rates (typical range 0.2–1.5 mm s⁻¹)
 - ⇒ More critical for cartridges than discs due to their variable and heterogeneous packing density (channelling)
 - ⇒ More critical when the sample volume exceeds the breakthrough volume as typical sampling devices provide too few theoretical plates for flow-independent retention
 - Sample properties
 - ⇒ Dilute viscous samples with a weak low viscosity solvent to reduce sample processing time
 - ⇒ Remove excessive particle matter by filtration or centrifugation to maintain a constant sample-processing rate. Concentrated hydrochloric acid is effective for dissolving inorganic particles in water samples
 - ⇒ Add small volume of organic solvent (1–3% v/v) to large volume water samples to ensure sorbent remains solvated and to maintain a constant (fast) sample-processing rate. Important for particle-loaded membranes
 - ⇒ Adjust pH to reduce ionization of weak acids and bases for reversed-phase sampling
 - ⇒ Maintain ionic strength approximately constant for samples and standards with reversed-phase sampling conditions. Ionic strength is a critical parameter for ion-exchange extraction
 - ⇒ Deproteinization of biofluids may be required for acceptable recovery of low molecular weight analytes for reversed-phase sampling
 - ⇒ Precipitation of inorganic acids (sulfate, phosphate, etc.) by barium hydroxide is sometimes required for acceptable recovery of organic acids from biofluids using ion-exchange extraction
 - Drying time (typically 1–5 min, but sometimes considerably longer)
 - ⇒ Sufficient to remove all sample solvent trapped in the sorbent pores
 - ⇒ Excessive drying may result in low recovery of analytes from evaporation or retention in poorly solvated regions of the sorbent
 - Rinse solvent (optional)
 - ⇒ Small volume of intermediate strength solvent to elute matrix components. Analytes remain immobilized on the sorbent
 - ⇒ Biological fluids, plant extracts and soil extracts often require a rinse step but surface waters may not
 - Eluting solvent (ideally 2–3 bed volumes but often larger)
 - ⇒ Should be a strong solvent able to displace all analyte from the sorbent in a small volume
 - ⇒ Should normally be volatile and miscible with the sample solvent
-

Future developments

Solid-phase extraction is approaching maturity and is a familiar laboratory operation for many analytical chemists. Advances are expected in the area of specific sorbents based on molecular imprinting or bioaffinity designed for the convenient isolation of target compounds in complex matrices. Advances are also expected in the use of computer-aided method development for the prediction of sampling and recovery conditions by simulation to replace tedious experimental trial-and-error approaches. A wider use and further development of automated solid-phase extraction systems can be expected, particularly in those industries where high sample throughput or round-the-clock process monitoring are important.

Solid-Phase Microextraction

J. Pawliszyn, University of Waterloo, Waterloo, Canada

Introduction

Solid-phase microextraction (SPME) was introduced as a solvent-free sample preparation technique in 1990. The basic principle of this approach is to use a small amount of the extracting phase (usually less than 1 μL) compared to the sample matrix. Sample volume can be very large, when the investigated system, for example air or lake water, is sampled directly. The extracting phase can be either a high molecular weight polymeric liquid, similar in nature to chromatographic stationary phases, or it can be a solid sorbent, typically of a high porosity to increase the surface area available for adsorption.

To date the most practical geometric configuration of SPME utilizes a small fused silica fibre, usually coated with a thin film of polymeric phase. The fibre is mounted for protection in a syringe-like device (Figure 1A). The analytes are absorbed or adsorbed by the fibre coating (depending on the nature of the coating) until an equilibrium is reached in the system. The amount of an analyte extracted by the coating at equilibrium is determined by the magnitude of the partition coefficient (distribution ratio) of the analyte between the sample matrix and the coating material.

In SPME, analytes typically are not exhaustively extracted from the matrix. However, equilibrium methods are more selective because they take full advantage of the differences in extracting phase/matrix distribution constants to separate target analytes from interferences. Exhaustive extraction can be achieved in SPME when the distribution constants are large enough. This can be accomplished for most compounds by cooling the fibre coating. This

concept was tested using a piece of microtubing coated on the outside instead of a solid rod and supplying liquid carbon dioxide into the tube to achieve an internally cooled fibre. In exhaustive extraction, selectivity is sacrificed to obtain quantitative transfer to target analytes into the extracting phase. One advantage of this approach is that, in principle, it does not require calibration, since all the analytes of interest are transferred to the extracting phase. On the other hand, the equilibrium approach usually requires calibration through the use of surrogates or standard addition to quantify the analytes and compensate for matrix-to-matrix variations and their effect on distribution constants.

Since equilibrium rather than exhaustive extraction occurs in microextraction methods, SPME is ideal for field monitoring. It is unnecessary to measure the volume of the extracted sample and therefore the SPME device can be exposed directly to the investigated system for quantitation of target analytes. Thin coatings of extracting phase result in fast separations. In addition, extracted analytes are introduced to the analytical instrument inlet system by simply placing the fibre in the desorption unit (Figure 1B and 1C). This convenient, solvent-free sample introduction process facilitates sharp injection bands and rapid separations. These features of SPME result in the integration of the first steps in the analytical process: sampling, sample preparation and introduction of extracted mixture to the analytical instrument. For example, total analysis time in field applications can be as low as a few minutes when portable instrumentation is used.

The equilibrium nature of the technique also facilitates speciation in natural systems since the presence of a minute fibre, which removes small amounts of target analytes, is not likely to disturb the system. Because of the small size, coated fibres can

be used to extract analytes from very small samples. For example, SPME has been used to probe for substances emitted by a single flower bloom during its lifespan.

Figure 1A illustrates the commercial SPME device manufactured by Supelco, Inc. (Bellefonte, PA, USA).

The fibre, glued into a piece of stainless steel tubing, is mounted in a special holder. The holder is equipped with an adjustable depth gauge, which makes it possible to control repeatably how far the needle of the device is allowed to penetrate the sample container (if any) or the injector. This is important, as the fibre can

be easily broken when it hits an obstacle. The movement of the plunger is limited by a small screw moving in the z-shaped slot of the device. For protection during storage or septum piercing, the fibre is withdrawn into the needle of the device, with the screw in the uppermost position. During extraction or desorption, the fibre is exposed by depressing the plunger, which can be locked in the lowered (middle) position by turning it clockwise (the position depicted in Figure 1A). The plunger is moved to its lowermost position only for replacement of the fibre assembly. Each type of fibre has a hub of a different colour. The hub-viewing window permits a quick check to be made of the type of fibre mounted in the device.

If the sample is placed in a vial, the septum of the vial is first pierced with the needle (with the fibre in the retracted position) and the plunger is lowered, which exposes the fibre to the sample. The analytes are allowed to partition into the coating for a predetermined time, and the fibre is then retracted back into the needle. When gas chromatography (GC) is used for analyte separation and quantitation, the fibre is inserted into a hot injector, where thermal desorption of the trapped analytes takes place (Figure 1C). All extracted compounds are introduced to the analytical instrument facilitating high sensitivity of determinations. The fibre desorption process can be automated by using an appropriately modified, commercially available syringe autosampler. For high performance liquid chromatography (HPLC) applications, a simple interface mounted in place of the injection loop can be used to re-extract analytes into the desorption solvent (Figure 1B). The extraction phase

can also coat the inner wall of the capillary. This approach to microextraction can be automated using a number of commercially available autosamplers, but it is limited to extraction of relatively clean samples, which do not plug capillaries.

The SPME device is suitable for both spot and time-averaged sampling. As described above, for spot sampling, the fibre is exposed to a sample matrix until equilibrium is reached between the sample matrix and the coating material on the fibre. In the time-average approach, on the other hand, the fibre remains in the needle during the exposure of the SPME device to the sample. The coating works as a trap for analytes that diffuse into the needle, resulting in the integration of concentration over given time.

SPME sampling can be performed in three basic modes: direct extraction, headspace extraction and extraction with membrane protection. Figure 2 illustrates the differences between these modes. In direct extraction mode (Figure 2A), the coated fibre is inserted into the sample and the analytes are transported directly from the sample matrix to the extracting phase. To facilitate rapid extraction, some level of agitation is required to transport the analytes from the bulk of the sample to the vicinity of the fibre. For gaseous samples, natural flow (e.g. convection) is frequently sufficient to facilitate rapid equilibration, but for aqueous matrices, more efficient agitation techniques, such as fast sample flow, rapid fibre or vial movement, stirring or sonication are required to reduce the effect of the depletion zone produced close to the fibre as a result of slow diffusional analyte

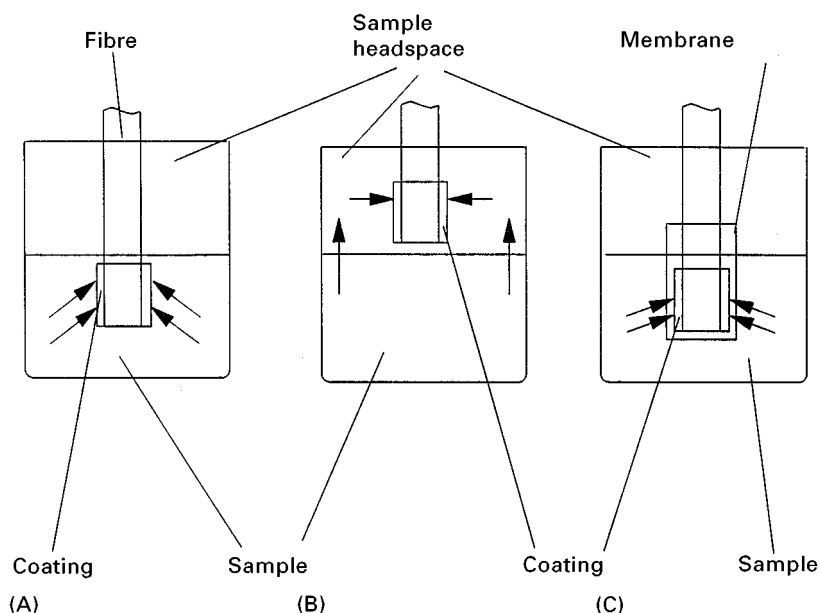

Figure 2 Modes of SPME operation: (A) direct extraction, (B) headspace extraction and (C) membrane-protected SPME.

transport through the otherwise static layer of liquid surrounding the fibre.

In the headspace mode (Figure 2B), the analytes are extracted from the gas phase equilibrated with the sample. The primary reason for this modification is to protect the fibre from adverse effects caused by non-volatile, high molecular weight substances present in the sample matrix (e.g. humic acids or proteins). The headspace mode also allows matrix modifications, including pH adjustment, without affecting the fibre. In a closed system consisting of a liquid sample and its headspace, the amount of an analyte extracted by the fibre coating does not depend on the location of the fibre, therefore the sensitivity of headspace sampling is the same as the sensitivity of direct sampling as long as the volumes of the two phases are the same in both sampling modes. Even when headspace is not used in direct extraction, a significant sensitivity difference between direct and headspace sampling can occur only for very volatile analytes. However, the choice of sampling mode has a significant impact on the extraction kinetics. When the fibre is in the headspace, the analytes are removed from the headspace first, followed by indirect extraction from the matrix. Therefore, volatile analytes are extracted faster than semivolatiles. Temperature has a significant effect on the kinetics of the process, since it determines the vapour pressure of analytes. In general, the equilibration times for volatile compounds are shorter for headspace SPME extraction than for direct extraction under similar agitation conditions, for the following reasons: (i) a substantial portion of the analytes is present in the headspace before the extraction process begins; (ii) there is typically a large interface between sample matrix and headspace; and (iii) the diffusion coefficients in the gas phase are typically higher by four orders of magnitude than in liquids. The concentration of semivolatile compounds in the gaseous phase at room temperature is small, consequently headspace extraction rates for those compounds are substantially lower. These rates can be improved by using efficient agitation or by increasing the extraction temperature.

In the third mode (SPME extraction with membrane protection, Figure 2C), the fibre is separated from the sample by a selective membrane, which lets the analytes through while blocking the interferences. The main purpose for the use of the membrane barrier is to protect the fibre against adverse effects caused by high molecular weight compounds when very dirty samples are analysed. While extraction from headspace serves the same purpose, membrane protection allows the analysis of less volatile compounds. The extraction process is substantially slower than direct extraction because the analytes

have to diffuse through the membrane before they can reach the coating. Use of thin membranes and increase in extraction temperature, applied to analysis of polyaromatic hydrocarbons (PAHs) in matrices containing humic matter, result in shorter extraction times.

Theoretical Aspects of Solid-phase Microextraction Optimization and Calibration

Thermodynamics

SPME is a multiphase equilibration process. Frequently, the extraction system is complex, as in a sample consisting of an aqueous phase with suspended solid particles having various adsorption interactions with analytes, plus a gaseous headspace. In some cases specific factors have to be considered, such as analyte losses by biodegradation or adsorption on the walls of the sampling vessel. In the discussion below we will only consider three phases: the fibre coating, the gas phase or headspace, and a homogeneous matrix such as pure water or air. During extraction, analytes migrate between all three phases until equilibrium is reached. The following discussion is limited to partitioning equilibrium involving liquid polymeric phases such as poly(dimethylsiloxane). The method of analysis for solid sorbent coatings is analogous for low analyte concentration, since the total surface area available for adsorption is proportional to the coating volume if we assume constant porosity of the sorbent.

The mass of an analyte extracted by the polymeric coating is related to the overall equilibrium of the analyte in the three-phase system. Since the total mass of an analyte should remain constant during the extraction, we have:

$$C_0 V_s = C_f^\infty V_f + C_h^\infty V_h + C_s^\infty V_s \quad [1]$$

where C_0 is the initial concentration of the analyte in the matrix; C_f^∞ , C_h^∞ and C_s^∞ are the equilibrium concentrations of the analyte in the coating, the headspace and the matrix, respectively; V_f , V_h and V_s are the volumes of the coating, the headspace and the matrix, respectively. If we define the coating/gas distribution constant as $K_{fh} = C_f^\infty / C_h^\infty$, and the gas/sample matrix distribution constant as $K_{hs} = C_h^\infty / C_s^\infty$, the mass of the analyte absorbed by the coating, $n = C_f^\infty V_f$, can be expressed as:

$$n = \frac{K_{fh} K_{hs} V_f C_0 V_s}{K_{fh} K_{hs} V_f + K_{hs} V_h + V_s} \quad [2]$$

Also:

$$K_{fs} = \frac{K_H}{K_F} = K_{fh}K_{hs} = K_{fg}K_{gs} \quad [3]$$

since the fibre/headspace distribution constant, K_{fh} , can be approximated by the fibre/gas distribution constant K_{fg} , and the headspace/sample distribution constant, K_{hs} , by the gas/sample distribution constant, K_{gs} , if the effect of moisture in the gaseous headspace can be neglected. Thus, eqn [2] can be written as:

$$n = \frac{K_{fs}V_fC_0V_s}{K_{fs}V_f + K_{hs}V_h + V_s} \quad [4]$$

The equation states, as expected from the equilibrium conditions, that the amount of analyte extracted is independent of the location of the fibre in the system. It may be placed in the headspace or directly in the sample as long as the volumes of the fibre coating, headspace and sample are kept constant. There are three terms in the denominator of eqn [4] which give measures of the analyte capacity of each of the three phases: fibre ($K_{fs}V_f$), headspace ($K_{hs}V_h$) and the sample itself (V_s). If we assume that the vial containing the sample is completely filled (no headspace), the term $K_{hs}V_h$ in the denominator, which is related to the capacity ($C_h^\infty V_h$) of the headspace, can be eliminated, resulting in:

$$n = \frac{K_{fs}V_fC_0V_s}{K_{fs}V_f + V_s} \quad [5]$$

Equation [5] describes the mass absorbed by the polymeric coating after equilibrium has been reached in the system. In most determinations, K_{fs} is relatively small compared to the phase ratio of sample matrix to coating volume ($V_f \ll V_s$). In this situation the capacity of the sample is much larger compared to capacity of the fibre, resulting in a very simple relationship:

$$n = K_{fs}V_fC_0 \quad [6]$$

The above equation emphasizes the field-sampling capability of the SPME technique. It is not necessary to sample a well-defined volume of the matrix since the amount of analyte extracted is independent of V_s as long as $K_{fs}V_f \ll V_s$. The SPME device can be placed directly in contact with the investigated system to allow quantitation.

Prediction of distribution constants In many cases, the distribution constants present in eqns [2]–[6] which determine the sensitivity of SPME extraction

can be estimated from physicochemical data and chromatographic parameters. For example, distribution constants between a fibre coating and gaseous matrix (e.g. air) can be estimated from isothermal GC retention times on a column with a stationary phase identical to the fibre-coating material. This is possible because the partitioning process in gas chromatography is similar to the partitioning process in SPME, and there is a well-defined relationship between the distribution constant and the retention time. The nature of the gaseous phase does not affect the distribution constant, unless the components of the gas, such as moisture, swell the polymer, thus changing its properties. A most useful method for determining coating-to-gas distribution constants uses the linear temperature programmed retention index (LTPRI) system, which relates retention times relative to the retention times of *n*-alkanes. The logarithm of the coating-to-air distribution constants of *n*-alkanes can be expressed as a linear function of their LTPRI values. For poly(dimethylsiloxane) (PDMS), this relationship is $\log K_{fg} = 0.00415 \cdot \text{LTPRI} - 0.188$. Thus, the LTPRI system permits interpolation of the K_{fg} values from the plot of $\log K_{fg}$ versus retention index. The LTPRI values for many compounds are available in the literature, hence this method allows estimation of K_{fg} values without experimentation. If the LTPRI value for a compound is not available from published sources, it can be determined from a GC run using a GC column coated with the same material as the fibre.

Estimation of the coating/water distribution constant can be performed using eqn [5]. The appropriate coating/gas distribution constant can be found by applying techniques discussed above, and the gas/water distribution constant (Henry's constant) can be obtained from physicochemical tables or can be estimated by the structural unit contribution method.

Some correlations can be used to anticipate trends in SPME coating/water distribution constants for analytes. For example, a number of investigators have reported correlation between the octanol/water distribution constant, K_{ow} , and K_{fw} . This is to be expected, since K_{ow} is a general measure of the affinity of compounds for the organic phase. It should be remembered, however, that the trends are valid only for compounds within homologous series, such as aliphatic hydrocarbons, aromatic hydrocarbons or phenols; they should not be used to make comparisons between different classes of compounds, because of different analyte activity coefficients in the polymer.

Effect of extraction parameters Thermodynamic theory predicts the effects of modifying certain

extraction conditions on partitioning and indicates parameters to be controlled for reproducibility. The theory can be used to optimize the extraction conditions with a minimum number of experiments and to correct for variations in extraction conditions, without the need to repeat calibration tests under the new conditions. For example, SPME analysis of outdoor air may be done at ambient temperatures that can vary significantly. A relationship that predicts the effect of temperature on the amount of analyte extracted allows calibration without the need for extensive experimentation. Extraction conditions that affect K_{fs} include temperature, inorganic salt concentration, pH and organic solvent content of the water.

Kinetics

The kinetic theory is useful to optimize the extraction conditions by identifying 'bottlenecks' in SPME and indicating strategies to increase extraction speed. In the discussion below we will limit our consideration to direct extraction (Figure 3).

Perfect agitation Let us first consider the case where the liquid or gaseous sample is well agitated. In other words, the sample phase moves rapidly with respect to the fibre, so that all the analytes present in the sample have access to the fibre coating. In this case, the equilibration time, defined as the time required to extract 95% of the equilibrium amount (Figure 4) of an analyte from the sample, corresponds to:

$$t_e = t_{95\%} = \frac{2(b-a)^2}{D_f} \quad [7]$$

Using this equation one can estimate the shortest equilibration time possible for a practical system by substituting appropriate data for the diffusion coefficient of an analyte in the coating (D_f) and the fibre-coating thickness ($b-a$). For example, the equilibration time for the extraction of benzene from a highly agitated aqueous solution with a 100 μm PDMS film is expected to be about 20 s assuming diffusion coefficient of $10^{-5} \text{ cm}^2 \text{ s}^{-1}$ in PDMS. Equilibration times close to those predicted for agitated samples have

Figure 3 Graphic representation of the SPME/sample system configuration, with dimensions and parameters labelled as follows: a , fibre coating inner radius; b , fibre coating outer radius; L , fibre coating length; d , vial inner radius; C_f , analyte concentration in the fibre coating; D_f , analyte diffusion coefficient in the fibre coating; C_s , analyte concentration in the sample; D_s , analyte diffusion coefficient in the sample; K_{fs} , analyte distribution coefficient between fibre coating and sample; $K_s = C_f/C_s$. (With permission from Louch *et al.* (1992) *Analytical Chemistry* 64: 1187.)

Figure 4 Mass absorbed versus time for a well-agitated solution of infinite volume. (With permission from Louch *et al.* (1992) *Analytical Chemistry* 64: 1187.)

been obtained experimentally for extraction of analytes from air samples (because of high diffusion coefficients in gases) or when high sonication power is used to facilitate mass transfer in aqueous samples. However, in practice there is always a layer of unstirred water around the fibre, although a high stirring rate will reduce its thickness.

Practical agitation Independently of the level of agitation, fluid contacting the fibre surface is always stationary, and as the distance from the surface increases, the fluid movement gradually increases until it corresponds to the bulk flow in the sample. To

model mass transport, the gradation in fluid motion and convection of molecules in the space surrounding the fibre surface can be simplified by a zone of a defined thickness in which no convection occurs, and perfect agitation in the bulk of the fluid everywhere else. This static layer zone is called the Prandtl boundary layer (**Figure 5**). Its thickness is determined by the agitation conditions and the viscosity of the fluid.

The equilibration time can be estimated for practical cases from the equation below:

$$t_e = t_{95\%} = 3 \frac{\delta K_{fs}(b-a)}{D_s} \quad [8]$$

where $(b-a)$ is the coating thickness on the fibre, D_s is the diffusion coefficient of the analyte in the sample fluid, K_{fs} is the distribution constant of the analyte between the fibre and the sample and δ is a boundary layer thickness. This equation can be used to predict equilibration times when the extraction rate is controlled by the diffusion in the boundary layer. The extraction time calculated using eqn [8] must be longer than the corresponding time predicted by eqn [7].

Conclusion

SPME is gaining acceptance principally because of its simplicity, speed and low cost of operation. The detection limits are comparable to a total extraction technique since all extracted analytes are introduced to the analytical instrument in SPME versus only a fraction for a total extraction techniques. Selectivity

Figure 5 Boundary layer model configuration showing the different regions considered and the assumed concentration versus radius profile for the case when the boundary layer determines the extraction rate.

Figure 6 Reconstructed GC-MS chromatogram indicating short chain fatty acids in a sewage sample. Peak assignment: 1, acetic; 2, propionic; 3, isobutyric; 4, butyric; 5, pivalic; 6, isovaleric; 7, valeric; 8, hexanoic acids. The peaks correspond to pyrenylmethyl esters of these acids.

of the technique is controlled by chemical properties of the coating and it is determined by the appropriate distribution constants. Selecting the appropriate fibre allows discrimination against interferences and therefore a separate clean-up step is not necessary. In addition, the coating can contain derivatization reagent, which can specifically bind target analytes, resulting in high specificity and sensitivity of the pro-

cess. **Figure 6** shows a chromatogram obtained after selective headspace SPME extraction of low molecular weight carboxylic acids from a sewage sample by poly(acrylate)-coated fibre containing 1-pyrenyl-diazomethane which selectively reacts with the target analytes. New coatings and reagents will allow expansion of SPME applications to new areas such as inorganic analysis and analysis of biomolecules.

Figure 7 Separation of purgeables A, B and C on a Vocol column. Conditions: 0° – $30^{\circ}\text{C min}^{-1}$ 70° ; 2.1 atm, dedicated injector, capacitor voltage 24 V, MS detector, mass range 45–250. Peak assignment: 1, chloromethane; 2, vinyl chloride; 3, bromomethane; 4, chloroethane; 5, trichlorofluoromethane; 6, 1,1-dichloroethene; 7, dichloromethane; 8, 1,2-dichloroethene; 9, 1,1-dichloroethane; 10, trichloromethane; 11, 1,1,1-trichloroethene; 12, tetrachloromethane; 13, benzene; 14, 1,2-dichloroethane; 15, trichloroethene; 16, 1,2-dichloropropane; 17, bromodichloromethane; 18, 2-chloroethyl vinyl ether; 19, *cis*-1,3-dichloropropene; 20, toluene; 21, *trans*-1,3-dichloropropene; 22, 1,1,2-trichloroethane; 23, tetrachloroethylene; 24, dibromochloromethane; 25, chlorobenzene; 26, ethylbenzene; 27, tribromomethane; 28, 1,1,2,2-tetrachloroethane.

In addition to solvent-free sample extraction, SPME is also a solvent-free sample introduction technique which facilitates design of a simple, low volume injection system. The net result is rapid desorption and good chromatographic separation, especially when flash-heated injectors are used. **Figure 7** illustrates 2.5 min extraction and separation of 28 Environmental Protection Agency volatile priority pollutants, which is over an order of magnitude faster than the standard purge and trap technique. This approach is particularly useful in combination with online SPME extraction. As eqn [6] indicates, it is possible to integrate sampling with a sample preparation step. This not only results in elimination of analyte losses to container walls and degradation during the transport, but also saves time and transport costs. This is particularly true when online SPME extraction is combined with field portable GCs.

Another interesting feature of SPME which is currently being explored includes speciation of analytes in complex matrices. The small amount of extracting phase does not disturb the equilibrium existing in the natural system and therefore allows quantitation of individual species or the determination of distribution

constants in a multiphase system. In addition, the fibre can be made very specific, so separation using chromatographic systems may not be necessary. Therefore development of coupling between SPME with other analytical instrumentation, such as mass spectrometry and inductively coupled plasma-mass spectrometry will facilitate high sensitivity and a large throughput.

Introduction

Separation involves removal of one or more of the constituent parts from a mixture. A solvent is that constituent of a solution that is liquid in the pure state, is usually present in the larger amount, and has dissolved the other constituent (a solute) of the solution. The solute may be a solid, a liquid or a gas. The solvent may be a single compound or a mixture of compounds. Solvent-based separation techniques become necessary when separation or removal of a solute(s) from a mixture become difficult or infeasible by conventional separation techniques such as distillation. If the addition of a solvent causes a totally miscible liquid to split into two liquid phases and produce the necessary property difference, the solvent-based separation technique is commonly known as liquid-liquid extraction. If the addition of a solvent causes the coexisting vapour and liquid phases to have different properties, the solvent-based

separation technique is called extractive distillation. **Figure 1A** and **1B** highlight the change of the mixture properties as a result of the addition of a solvent. In **Figure 1A**, the difference between the properties of the liquid and vapour for the binary azeotropic mixture of ethanol-water with and without the addition of solvents is highlighted. It is clear from **Figure 1A** that addition of a solvent removes the barrier of the azeotropic condition. **Figure 1B** highlights through a ternary diagram that addition of the solvent causes the totally miscible binary liquid mixture (components 1 and 2) to split into two liquid phases, a solvent-rich phase and a solute-rich (1 or 2) phase.

Examples of industrial processes employing solvent-based separation techniques are numerous. Almost all chemical, petrochemical, biochemical and pharmaceutical processes employ one or more solvent-based separation techniques. In chemical and petrochemical processes, solvents are used mainly to separate components from liquid and/or gaseous mixtures, while in biochemical and pharmaceutical processes, solvents are typically employed for dissolving or removing solids. Use of a solvent to extract aromatic compounds from a petroleum by-product

Table 1 Classification of important solvent-based separation techniques

<i>Separation technique</i>	<i>Solute property</i>	<i>Number and identity of phase</i>	<i>Separation barrier</i>	<i>Separation phenomena</i>	<i>Solvent function</i>
Liquid-liquid extraction	Totally miscible solutes	Two liquid phases	Total miscibility	Property differences in liquid phases	Addition of solvent causes phase split
Extractive distillation	Solutes from azeotrope or are close boiling	Vapour and liquid phases	Azeotropes or relative volatilities	Property differences in vapour and liquid phases	Addition of solvent breaks the azeotrope but does not cause liquid phase split
Azeotropic distillation	Solutes from azeotrope or are close boiling	Vapour and two liquid phases	Azeotropes or relative volatilities	Property differences in vapour and two liquid phases	Addition of solvent breaks the azeotrope but also causes liquid phase split
Absorption	Absorbed gases in liquid	Vapour and liquid phases	Solubility of gases	Differences in solubility	Solvent must be able to dissolve the solute (gas)
Stripping	Entrained liquids in gases	Vapour and liquid phases	Solubility of liquids	Differences in solubility	Solvent must be able to dissolve the solute (liquid)
Leaching	Solid particles	Solid(s) and liquid phase	Solubility of solids	Differences in solubility	Solvent must be able to dissolve the solute (solid)

or removal of a chemical species (undesirable by-product or raw material) from a wastewater stream through solvent-based separation are typical examples of industrial application. Figure 1C illustrates the removal of phenol from water through solvent based liquid-liquid extraction. An important feature in this and most other vapour-liquid and/or liquid-liquid solvent-based separation techniques is that the solvent is recovered and recycled back to the solvent-based separation unit.

A logical criterion for classification of solvent-based separation techniques is the number and identities of the coexisting phases and the function of the solvent. Table 1 gives a list of some of the well-known solvent-based separation techniques, classified in terms of the number and identities of the coexisting phases and function of the solvent. It can be noted from Table 1 that the selected solvent is directly related to the separation task and the separation technique and indirectly related to factors such as cost of operation, the efficiency of separation and the environmental impact. Therefore, solvent selection plays an important role in solvent-based separation. While solvents and solvent-based separation techniques have been known for a very long time, use of efficient search techniques, such as computer-aided molecular design (CAMD) and computer-aided database search, are fairly new. This article highlights the computer-aided methods and tools related to solvent selection.

Solvent Selection: Problem Formulation

Problem formulation is an important first step in solvent selection as it is necessary first to define the functions of the solvent before attempting to find suitable candidates. Each problem, characterized in terms of solvent and solute properties, needs to address a set of issues related to separation task, performance, environmental impact and problem-specific (special) considerations. The solvent selection problem is formulated in terms of a set of properties (target properties) and their values (target values). A two-step procedure, consisting of a problem identification step (identifies the solvent functions and issues that need to be addressed) and a criteria for evaluation step (selects target properties and their target) is recommended.

Properties

The properties of the selected solvent define, to a large extent, the type of the solvent-based separation technique. Consider the binary azeotropic mixture of ethanol-water and the solvents benzene or ethylene glycol. If benzene is used as the solvent, the resulting solvent-based separation process is called azeotropic distillation because ethanol-water-benzene forms a heterogeneous azeotropic system, as shown in Figure 2A. If, on the other hand, ethylene glycol is used as a solvent, the solvent-based

Figure 2 (A) Ternary VLE diagram for ethanol–water–benzene (solvent). (B) Ternary homogeneous VLE diagram for ethanol–water–ethylene glycol (solvent). Key: ..., heterogeneous liquid boiling surface; ○, vapour line; △, critical point; □, azeotropes. All temperatures in °C.

separation technique is called extractive distillation because ethanol–water–ethylene glycol forms a homogeneous azeotropic system, as shown in Figure 2B.

Table 2 gives a list of different types of solvent properties that may be considered in the selection/design of a solvent. These properties are classified in terms of pure component, mixture and environmental. Table 3 expands on the nature of the environmental properties. While the pure component and environmental properties are usually available for a large number of chemical species, the mixture properties usually need to be estimated through suitable property prediction methods.

Problem Identification

Solvents are well known for their different applications and, therefore, functions. They may be employed as cleaning agents, as paint additives, as separ-

ating agents and many more. Each application of the solvent is related to different sets of desirable functions and undesirable effects (or functions). The main question that needs to be asked here is what functions will the selected solvent perform? The answer depends, to a large extent, on the properties of the solute and/or the mixture to be separated. Properties, for pure compounds and mixtures, provide a framework for classifying the different solvent functions and their undesirable effects in a systematic and structured way.

Criteria for Evaluation

Since in solvent selection problems, one is looking for alternatives that match approximately the desirable solvent functions but not the undesirable solvent effects, numerical values of properties can be used to evaluate candidate solvents. Based on the identified separation task, the question of which properties (target properties) should be considered in defining the solvent functions and what should be the property values (target values) is addressed in this step. The exact target values for the target properties are obtained by trial and error. However, if a known solvent is being substituted, then the target values are obtained from the solvent that needs to be substituted. In Table 2, two types of criteria for evaluation are shown – simple and general. As simple, the minimum number of properties that may define the desired solvent properties for each solvent based separation is highlighted, while as general, a comprehensive list of properties is highlighted.

Example

Consider the process from Figure 1C – the effluent water stream from an industrial process contains 7% w/w of phenol, which needs to be removed through liquid–liquid extraction. The desired solvent, when added to the phenol–water system, must cause a phase split such that the solvent-rich phase will contain significantly more phenol than water while the water-rich phase will contain very little phenol or solvent. It should be possible to separate easily the solvent from phenol. That is, the solvent must not form azeotrope, it must have a reasonable difference in boiling point and vapour pressure from phenol, and it must have a density lower than that of water in order to have free convection flow in the extraction column. If the solvent has a high environmental impact, the loss of the solvent through the water-rich phase will have to be reduced. If the solvent is unable to remove enough phenol, more solvent may need to be used. It should pose a low risk of explosion (the flash point temperature should be as high as possible).

Table 2 Solvent selection problem formulation with properties

Property	Solvent design

To ensure a minimal loss of the solvent to the water stream, the solvent should have very low miscibility in water and a high octanol–water partition coefficient. It should be possible to separate the solvent easily from phenol (must not form azeotrope, must

have a reasonable difference in boiling point and vapour pressure from phenol, and must have a density lower than that of water in order to have free convection flow in the extraction column). For the process in Figure 1C, the target properties and their target values are given in Table 4.

Solvent Selection: Methods and Tools

Methods

Solutions of solvent selection problems formulated above require a multistage approach (see Figure 3).

Table 4 Problem formulation for separation of phenol from wastewater

Target property	Target value
Partition coefficient (log <i>P</i>)	> 1.5
Solvent loss	< 0.0015
Liquid density at 298 K	< 0.95
Normal boiling point	< 450 K
Vapour pressure at 360 K	> 0.03 bar
Flash temperature	> 300 K
Selectivity	> 8
Capacity	> 2
Separation factor	> 80
Other properties	Must not form azeotrope with phenol
	Acceptable environmental properties

Figure 3 Multilevel approach to solvent selection.

After problem formulation, a list of feasible solvent alternatives is determined and ordered according to a specified criterion. The best feasible candidates are then analysed in terms of separation task, performance, environmental impact and special considerations in order to determine the most appropriate solvent(s). If none are found, it is necessary to go back to the problem formulation stage and relax some target property values or go back to the stage for determination of alternatives and use another search space. Thus, solvent selection is also a design problem requiring a trial-and-error solution approach.

List of solvent alternatives Determination of the list of solvent alternatives is based on the 'generate and test' paradigm. That is, first generate a list of solvent candidates and then analyse (test) the candidates to determine those that match the specified target property values. The methods available can be classified into three types: database search, CAMD and hybrid.

The database search approach involves a search in one or more databases for compounds that match the specified target property values. For this approach, an efficient search engine (or computer-aided technique) is needed. For solvent selection problems involving only pure component target properties, efficient search engines based on so-called pattern matching are available. Difficulties are encountered, however, when mix-

ture properties are also included in the target properties and when the databases do not contain all the target properties for all the compounds. In such cases, an efficient and comprehensive search is almost impossible and reliable property estimation methods are needed.

In the CAMD technique, molecular structures of chemically feasible compounds are generated, the specified target properties for the generated molecules are estimated and those that match the specified target property values are included in the list of alternatives. The CAMD technique is therefore a more efficient search technique that is able to overcome the difficulties related to solvent selection problem formulations involving pure component as well as mixture target properties and incomplete databases. CAMD techniques, however, depend on the accuracy of the property estimation methods used for prediction of target properties for the generated molecules. The search space is not limited by the molecules present in a database but by the number of molecular structures that can be generated and by the application range of the property estimation methods used.

Combining the search based on databases with CAMD, a multilevel hybrid approach is obtained. In this approach, in level 1, a database search is carried out only with respect to the pure component target properties. This gives an idea of the types of molecules that are likely to be selected as solvents. Level 2

uses this information as initial estimate and employs CAMD to solve the solvent selection problem for the pure component and mixture properties that it can estimate with acceptable accuracy. At the end of level 2, a larger list of alternatives than level 1 is obtained. In level 3, those molecules that can be found in the database are identified and their target properties are verified, resulting in an updated list of alternatives. This list is now used for checking the remaining target properties (such as environmental properties and special properties that are found in special databases). Screening out the molecules that do not satisfy the target properties based on these databases produces a further refinement of the list of alternatives. Finally, in level 4, selected molecules from level 3 are investigated in terms of atomic structure, bond length, bond angle, energies, etc., through links to molecular modelling programs.

Final selection Since the list of alternatives contains more than one solvent, all of which match the specified target property values, it is necessary to determine the most appropriate solvent from this list. Therefore, it is necessary to define a selection criterion, for example, an objective function (F) that is either minimized or maximized. This objective function may be an explicit function of the target properties (see eqn [1]) or an implicit function of the target properties (see eqn [2]):

$$F = (S_p, S_s) \quad [1]$$

$$F = f(D_s(S_p, S_s), T(S_p, S_s), P(S_p, S_s)) \quad [2]$$

In the above equations, S_p is solvent power, S_s is selectivity, D_s is a vector of specified products, T is a vector of operating temperatures and P is a vector of operating pressures. Since the target properties of eqn [1] are known for the solvents in a generated and tested list of alternatives, use of eqn [1] simply means ordering the molecules in ascending order and selecting the optimal for further analysis (for example, pilot plant study). In this case, the solvent with the maximum value of F is regarded as the optimal solvent. In eqn [2], the evaluation of F needs other calculations (such as process simulation) in order to determine the values of D_s , T and P corresponding to an optimal F . Two solution approaches are commonly applied – an enumeration approach and a simultaneous solution approach. In the enumeration approach, the optimal value for F in eqn [2] is determined for each solvent through process simulation/optimization, generating a set of values for F , D_s , T and P corresponding to each solvent in the generated list of alternatives. The optimal solvent then corresponds to the minimum (or maximum) F in the

generated set. In the simultaneous solution approach, the solvent identity is an integer variable and adding it as an optimization variable in the process optimization problem gives a mixed integer nonlinear programming (MINLP) problem formulation, which determines the optimal solvent and the optimal F simultaneously.

Tools

From the above section, it is clear that the tools that are needed for solution of the solvent selection problem are databases, search engines, property estimation methods, process simulators and numerical methods (such as a MINLP-solver). It should be noted that all the tools might not be necessary for all solvent selection problems. Also, different sets of tools are needed depending on the chosen method of solution. In this article, only the use of search engines with the hybrid approach, which includes database search, CAMD and property prediction, is highlighted. Table 5 gives a list of various tools that may be used in solving solvent selection problems.

Search engine The hybrid generate-and-test approach (search engine–CAMD algorithm) has four levels. Each level has its own generate-and-test algorithms. Higher levels use additional molecular structural information compared with lower levels. Levels 1–2 are group contribution based (thereby employing macroscopic representation of the molecule), while levels 3–4 are based on atomic (microscopic) representation of the molecule. Switch from level 1–2 to 3–4 needs a conversion of macroscopic representation to microscopic representation.

Level 1 This level generates sets of building blocks (*fragments*) by combining first-order functional groups. These sets are capable of forming at least one feasible molecular structure. Simultaneous calculation of related properties (that are dependent only on first-order groups) and screening of the generated structures is performed to control the problem size and execution time. The algorithm here is based on a modified set of rules. Building blocks are classified according to type. Feasibility rules are based on the number of groups from a specific class a compound may contain. Valency rules are used to determine the number of groups with one, two, three and four connections that are to be used in molecule structure generation. The main steps of the level 1 algorithm are illustrated in Figure 4.

Level 2 This level generates molecular structures by combining elements of the individual fragment sets

Table 5 List of tools for solvent selection problems

from level 1 to form molecular structures. First- and second-order groups are considered. The main feature of this algorithm is that it is pseudorecursive, all allowed combinations are considered, and efficiency is maintained by continuous removal of duplicate structures. Also, the combination rules satisfy conditions of chemical feasibility. Use of second-order groups allows the estimation method to differentiate between some isomers.

Level 3 In this level, the selected candidates from level 2 are given an atomic representation. Note that

the atomic representation also defines the connectivity of the molecules. Therefore, property prediction methods based on connectivity indices can be employed to predict properties that could not be predicted earlier (due to unavailable group contributions) or to verify previously estimated values.

Level 4 In this level, generation and testing enters an interactive mode. For any selected candidate from level 3, it is possible to use molecular modelling programs such as MOPAC or Chem3D from Cambridge Soft Corp. A three-dimensional graph (or

**Figure 4** Hybrid CAMD search engine.

molecular model) is created by applying a set of standard or default bond lengths and angles for the various types of connections. As a result the true molecular model of a compound, which can be further analysed in terms of conformers, stability, properties, etc., is obtained.

Application Examples

Problems

Solutions of solvent selection problems with the database search approach and the hybrid approach are illustrated. Tools listed in Table 5 have been used for solution of these problems, which involve solvent-based vapour-liquid, liquid-liquid and solid-liquid separations. For the removal of morphine, all the solution steps for solvent selection with the hybrid approach are highlighted. For the other examples, only the problem formulation in terms of target properties and the final results are presented. Also, for solution with the database search approach, only pure component target properties have been considered.

Database Search Approach

For the separation of phenol from water by liquid-liquid extraction, solution of the problem (as defined in Table 4) finds, among others, butyl acetate and toluene as solvents that match the pure component target properties.

For the purification of ethanol from a binary mixture of ethanol-water, solvents for extractive or azeotropic distillation are sought. The pure component target properties are: normal boiling point (T_b) < 473 K; melting point (T_m) > 270 K; flash point (F_T) > 320 K; solubility parameter (δ) between 15 and 20 MPa^{1/2} for azeotropic distillation or 28 and 35 MPa^{1/2} for extractive distillation. Note that δ of ethanol is around 26 MPa^{1/2} and that of water is around 47.8 MPa^{1/2}. A value of δ far from water and closer to ethanol will be selective to ethanol and will likely cause a phase split. Benzene, toluene and cyclohexane satisfy the target property values for azeotropic distillation. Ethylene glycol satisfies the requirements for extractive distillation. Figure 2A and 2B also confirm this result.

For the separation (removal) of phenol present as a solid, a solvent is needed to dissolve it. The solvent target properties may be defined with T_m > 270 K, T_b < 473 K and $23.5 < \delta < 25.5$ MPa^{1/2}. A search of the database gives furfuryl alcohol, aniline, *N,N*-dimethylformamide and furfural. The solvent function of aniline related to dissolving solid phenol is validated through the computed solid-liquid phase diagram for the phenol-aniline mixture (see Figure 5).

Figure 5 Computed SLE phase diagram for aniline-phenol.

Hybrid Approach

The solvent selection problem for the removal of phenol from wastewater has been solved with the ProCAMD (see Table 5). The summarized results from ProCAMD are shown in Figure 6. Compared with butyl acetate and toluene, this solvent has been found to have a higher F (eqn [1]) and is environmentally acceptable.

Identification of a solvent for morphine

Problem formulation In the production of morphine a solvent is needed for dissolving the solid. Known solvents for morphine include cyclohexane, tetrachloromethane, toluene and benzene. It is desired to find alternative solvents capable of dissolving morphine. Furthermore, in order not to contaminate the product with toxic substances, in case of solvent inclusions after crystallization, the compound should be nonaromatic and have a low toxicity.

Constraint selection Solubility is a mixture property. To be able to predict solubility to some degree of accuracy it is necessary to have access to a method for calculation of activity coefficients. For complex compounds (such as morphine) very few group-contribution-based property estimation methods are able to describe the molecular structure (see Figure 7). Therefore, the search for alternative solvents is carried out using pure component properties as criteria for evaluation. It is well known that two compounds having similar solubility parameters (δ) are highly likely to be miscible. The search for solvents for morphine can therefore be expressed as a search for compounds being liquid at ambient temperatures and having a solubility parameter as close as possible to that of morphine ($\delta = 26.3$ MPa^{1/2}).

Figure 6 Results for phenol-wastewater separation (screenshot from ProCAMD).

Design specifications

- *Compound type* acyclic alkanes, ethers, esters, aldehydes, ketones, alcohols;
- $T_b > 350$ K; $T_m < 273$ K;
- $22 < \delta < 30$ (exclusion of the lowest ranking candidates);
- *performance measure* $|26.3 - \delta|$ should be as low as possible.

Generation of alternatives The ProCAMD package (see Table 5) was used, generating 348 candidates fulfilling the requirements. After performing a structure search to identify substances with known CAS registry numbers two candidates, 1,5-pentanediol and acetol, were selected based on having a solubility parameter close to that of morphine.

Figure 7 Molecular structure of morphine.

Analysis and verification To verify the predicted values of the properties used as design specifications a search in available databases was carried out and the experimental values compared to the predicted. Furthermore the RTECS database (see Table 5) was consulted in order to investigate the health and environment properties of the selected compounds. The result of the investigations and the predicted properties are shown in Table 6.

Candidate selection From the data listed in Table 6 it is clear to see that among the known and generated solvents 1,5-pentanediol is the most promising candidate and should be selected for further testing in an experimental setting.

Future Developments

As current and future separation problems become more difficult due to complex molecular structure of solutes, changes in environmental regulations and demands for material and energy conservation, the solvent selection problem is also becoming more difficult. It is no longer feasible to attempt to solve the solvent selection problem with a single database. Computer-aided techniques provide the necessary framework to solve the current and future solvent selection problems. The current hybrid approaches,

Table 6 List of solvents for separation of morphine

Solvent	CAS-NO	Predicted			Experimental			Compound class (RTECS)
		T_b (K)	T_m (K)	δ (MPa ^{1/2})	T_b (K)	T_m (K)	δ (MPa ^{1/2})

D, drug; S, primary irritant; T, reproductive-effector; M, mutagen; C, tumorigen.

however, need to integrate aspects of molecular modelling and computational chemistry before acceptable solutions to problems involving complex solutes and tight environmental regulations can be obtained. Finally, it should be noted that having a good solvent means easier design/operation of the solvent-based separation technique. Therefore, it is important to formulate correctly the solvent selection problem and to find reliable results in the form of optimal solvents.

Sample preparation is nowadays the limiting step in the trace analysis of organic pollutants in environmental and biological samples. Looking forward to the laboratory of the future, versatile and universal sample enrichment techniques are required, which can produce fast and valid data, with low costs in terms of solvent consumption and operator involvement. A selectivity higher than that of the classical exhaustive extraction methods or the simultaneous elimination of the interference material could be an additional requirement, as it would reduce the amount of solvents and adsorbents used by reducing or eliminating the subsequent clean-up step. Possible additional benefits deriving from a low manual manipulation of the samples would be a reduction in the

risk of contamination and loss of the analytes, as well as an easier automation of the process.

Steam distillation extraction-solvent extraction (SDE) has been presented as such a universal sample enrichment technique. SDE allows the simultaneous extraction, clean-up and concentration of the target compounds in a closed system, with short analysis times (1–8 h) and by using small amounts of organic solvents (a few mL). This paper reviews this assumption for the case of the analysis of less volatile organic pollutants in environmental samples. The SDE advantages and shortcomings for such an analysis have been discussed.

Introduction

The monitoring of toxic organic chemicals in environmental and biological samples is a major concern in many different fields. However, the large variety of compounds of interest, the differences existing in

their environmental levels and physico-chemical properties, and the complexity of the matrices typically investigated make the development of universal analytical methods for such an analysis a very difficult goal. This is especially true for the most toxic organic pollutants as their high toxicity makes their reliable detection and accurate quantification at the trace level more relevant.

Most of the procedures described in the literature for the analysis of less volatile organic pollutants are time-consuming, laborious and specific for the determination of an analyte (or family of compounds) in a selected matrix. Examples of selective extraction of the target compounds, allowing their determination without any additional clean-up, can be found in the literature. However, most of these procedures involve sophisticated and expensive analytical techniques, such as supercritical fluid extraction or gel permeation chromatography. On the other hand, the efficiency of these methods have been recognized to be highly matrix-dependent. Because of these unresolved shortcomings, classical exhaustive extraction techniques, i.e. liquid-liquid extraction, LLE, solid-liquid extraction or Soxhlet extraction, are still widely used in official methods and routine applications. Due to the low selectivity of these methods, subsequent elimination of the co-extracted material is recommended. Such a clean-up step is mandatory for reliable trace level determination of lipophilic and bio-accumulative pollutants in biological and complex environmental samples.

Steam distillation-solvent extraction (SDE) has been used mainly for the extraction and concentration of fragrance and flavour compounds. However, a variety of SDE methods reporting sample preparation for the analysis of pollutants in environmental samples can be found in the literature. Most of these methods allow the simultaneous extraction, clean up and concentration of the target compounds. The investigated compounds range from volatile polar and non-polar pollutants to non-ionic surfactants. This article reviews the suitability and the limitations of SDE for the determination of less volatile trace organic pollutants, such as pesticides, polychlorinated biphenyls (PCBs), polychlorinated dibenzo-p-dioxins and furans (PCDD/Fs), or surfactants, in environmental and biological matrices. The most relevant variables affecting the efficiency of the SDE of these compounds are discussed and the results of some selected applications reviewed.

General Considerations

According to the theoretical model developed by Rijks *et al.*, in 1983, the efficiency of the SDE process

increased with the extraction time and with the liquid and vapour flows. The process also depends on analyte-specific parameters related to the activity coefficient (calculated from the water solubility of the analyte at 100°C) and the gas-liquid distribution coefficient of the compound in water at the process temperature (i.e., 100°C for water steam). Not unexpectedly, the recoveries increased with the affinity of the target compounds for the extracting solvent. This theoretical model is applicable only under ideal conditions, which are achieved when all volumes and flow rates remain constant and there is ideal mixing and equilibrium at every stage. In spite of these limitations, the model reflects the effect of several experimental factors on the SDE process. In fact, the different modifications carried out on the SDE devices originally described by Likens and Nickerson in 1964 and by Flath and Forrey in 1977 reveal the influence of several parameters on the recoveries of the target compounds. The modifications were mainly focused on increasing the size of the vapour chamber and/or the condensing surface to allow a more complete mixing of the solvent and steam vapours, as well as on the miniaturization of the system. As a consequence of the changes in design (Figure 1), the efficiency of the extraction was increased, the analysis time reduced and the field of SDE expanded through the analysis of residue levels of less volatile pollutants in environmental samples.

Due to the characteristics of the technique, the feasibility of SDE for the analysis of less volatile compounds depends on their (i) potential for forming azeotropes with water and (ii) relative solubility in water and in the extraction solvent. However, the SDE of the target compounds from complex samples can be expected to occur only after destruction or degradation of the main matrix components, which usually entrap the analytes (see below). Therefore, as stated by Nash in 1984, the applicability of the SDE technique to the analysis of this kind of environmental matrices would be limited by the resistance of the investigated compounds to the selected degradation procedure. Alternatively, in some cases, co-distillation solvents have been used to improve the SDE efficiency by reducing the surface tension of the water and by increasing the extraction power (polarity) of the organic solvent. Finally, rather different results have been published about the suitability of adding anti-foam agents in applications involving fatty samples (see Table 3).

Application of SDE to the Analysis of Aqueous Samples

Water was one of the first environmental samples selected to evaluate the feasibility of the SDE

Figure 1 A typical SDE modern design.

technique for the determination of less volatile organic contaminants levels. **Table 1** summarizes relevant data concerning some reported methods for the analysis of this matrix.

Quantitative recoveries of spiked organochlorinated pesticides, OCPs (globally, in the range 90–106 ppb), and PCBs (globally, in the range 70–104 ppb) in aqueous samples have been reported using the SDE technique. The reported methods allowed the simultaneous extraction and concentration of the analytes in 1–1.3 h in a relatively small amount of a non-polar solvent (1–15 mL). Usually, no additional treatment of the sample or the organic extract was required. The SDE technique was favourably compared with other widely used extraction procedures, such as LLE or solid-phase extraction (SPE) by Ramos *et al.* in 1995, e.g. similar recoveries have been published for the analysis of PCBs in water at the ppb (ng mL^{-1}) level by using SDE, LLE or SPE. However, the higher repeatability of the SDE procedure (relative standard deviations, RSD, lower than 10%) and

the small amount of organic solvent involved, as well as the short sample preparation times, makes SDE a valuable alternative technique for such an extraction, especially when a large number of analyses have to be carried out.

Nevertheless, some limitations of SDE have also been reported for less volatile pollutants in water samples. Nash *et al.* in 1984 studied different parameters affecting the efficiency of the steam distillation process. They concluded that this technique is probably limited to compounds with a vapour pressure of about 1 kPa at 100°C. Their results also showed that the performance of SDE depends on the concentration investigated and that recoveries tend to increase with the spiking level.

Similar tendencies have been observed by Ramos *et al.* in 1995 when using the SDE technique for the extraction of water spiked with the 2,3,7,8-substituted-CDD/Fs at different levels of concentration ($0.25\text{--}2\text{ ng mL}^{-1}$, $0.025\text{--}0.2\text{ ng mL}^{-1}$ and $0.0025\text{--}0.02\text{ ng mL}^{-1}$). The recoveries obtained for the lower and higher boiling point congeners (tetra- and octa-CDD/Fs, respectively) are consistently lower than those found for the rest of the investigated congeners: respectively 40–76% and 73–137% at the highest level of concentration investigated, 39–60% and 62–92% at the intermediate, and 37–55% and 25–72% at the lowest spiking level. These results also show that the SDE recoveries for a given compound decrease with the concentration level when using *n*-pentane as the extraction solvent. The simple substitution of *n*-pentane for a solvent more selective for the PCDD/Fs (dichloromethane) increases recoveries from 25–73% to 71–139% for tetra- to hepta-CDD/Fs at the $0.0025\text{--}0.02\text{ ng mL}^{-1}$ level. However, no additional improvement is obtained for the octa-CDD/F recoveries (38–56%). In spite of the low recoveries obtained for OCDD/F, the proposed SDE procedure compares favourably with results previously published by using LLE or SPE in terms of repeatability, analysis time and solvent consumption.

Good recoveries (in the range 84–100%) have been reported by Meissner *et al.* for the analysis of surfactants such as fatty alcohol sulfates and alkyl polyglycosides in water (**Table 1**). SDE of the fatty alcohols yielded by hydrolysis and subsequent LLE of the original compounds is an attractive technique for the effective clean-up and concentration of these complex mixtures of compounds at the trace level. On the other hand, the application of SDE to the extraction of fatty alcohol ethoxylates with more than three ethoxy units in the molecule cannot be accomplished due to their high solubility in water.

Table 1 SDE methods for the analysis of less volatile organic pollutants in aqueous samples

Application of SDE to the Analysis of Non-Fatty Environmental Samples

Table 2 summarizes relevant data related to some reported SDE methods for the analysis of less volatile organic pollutants in non-fatty environmental samples. Most of the reported SDE applications referred to the analysis of OCPs and toxic aromatic compounds, e.g. PCBs, polychlorinated naphthalenes (PCNs), or polynuclear aromatic hydrocarbons (PNAs), in soils and sediments. Contrary to what might be expected from the high complexity of these samples, most of the methods did not include any further pre-treatment of the matrix but blending with the selected volume of water. Only a few procedures involving drastic treatments (e.g. blending of the sample with H₂SO₄ and K₂Cr₂O₇) during the SDE to guarantee the destruction of the soil or sediment components in which the target compounds could be entrapped, can be found in the literature.

The efficiency (or need) of such a drastic treatment is difficult to evaluate from the data published. In general, high (quantitative) recoveries have been reported for freshly spiked analytes (globally in the range 78–102% for PCBs and OCPs at the 20–90 µg g⁻¹ level) with all the procedures (Table 2).

However, the efficiency of the proposed SDE methods for the extraction of endogenous pollutants from weathered samples has been scarcely evaluated. In these studies, Seidel *et al.* (1993) and Cooke *et al.* (1980) found concentrations very close or below the limit of detection have usually been reported for the endogenous contaminants, but the lack of comparison of the SDE results with those obtained by standard or more exhaustive methods, i.e. Soxhlet extraction, do not allow any discussion about the methods used.

Dunnivant *et al.* in 1988 reported recoveries ranging from 47 to 99% for SDE of certified sediments with PCBs at the 2.34–24.6 µg g⁻¹. However, as quoted above, this SDE method involved a digestion of the sample under drastic conditions.

In a closely related study, Nash *et al.* compared the efficiency of steam distillation with subsequent organic solvent extraction to that of Soxhlet extraction for the analysis of pesticides in soil, plant tissues and air (polyurethane foam filters). Both procedures provided similar recoveries for the spiked samples (in the ranges 80–90%, 80–90% and 90–100%, respectively). However, the SDE levels determined for weathered soils blended with water were 40–50% lower than the concentrations found by the Soxhlet procedure. The study also showed that the efficiency

of the SDE depends on the soil type and, in agreement with that mentioned for aqueous samples, on the volatility of the selected compounds. The less volatile the compound, the lower the recovery: SDE recoveries for DDT were only 21–60% of those found by Soxhlet extraction.

Onuska and Terry observed a similar trend when comparing the SDE and the Soxhlet efficiencies for the extraction of spiked chlorinated benzenes from a sediment. The concentrations found using SDE were 14–36% lower than those using the Soxhlet method, except for pentachlorobenzene and 1,3-dichlorobenzene, which were not determined by the latter procedure. The authors also reported a decrease in the SDE recoveries of the target compounds as the investigated concentration level decreased (Table 2). The recoveries of the studied chlorinated benzenes decreased from 76–91% to 66–89% as the spiking level decreases from 100–1000 $\mu\text{g g}^{-1}$ to 1–10 $\mu\text{g g}^{-1}$.

In a recent study, Meissner *et al.* used SDE for the determination of fatty alcohol sulfates in cosmetics (toothpaste) by combining this technique with a hydrolysis treatment. However, the application of SDE to the analysis of nonylphenol polyethoxylates in sewage sludge by Lee *et al.* failed when compared with the more efficient supercritical fluid extraction technique.

In general, the published SDE methods for the analysis of non-fatty environmental samples involve longer extraction times (1–8 h) than those reported for aqueous samples (1–1.3 h). In addition, and contrary to that proposed by the theoretical model of Rijks *et al.*, the recoveries of less volatile compounds from non-fatty complex samples have been found to be independent of the vapour flow rates. However, it is important to note that in this study by Seidel ethanol was added to the water flask to improve the OCP recoveries, and that the possible effect of a co-distillation solvent was not included in the theoretical model.

Application of the SDE to the Analysis of Fatty Biological Samples and Food

Due to the high lipophilicity of some of the most toxic pollutants, such as OCPs, PCBs and PCDD/Fs, the classical procedures for the analysis of these pollutants in fatty samples were based on an exhaustive extraction of the lipids from the matrix. Subsequent removal of the co-extracted lipids has been widely recognized as the main problem with these kinds of methods, especially when analysing samples with high fat contents such as dairy products. Because of the characteristics of the SDE technique, the disruption of the strongly bound pollutant-matrix in these

samples can be accomplished before SDE by degradation of the matrix components entrapping the target compounds. Treatment with 1–2 M sulfuric acid followed by ultrasonication in a bath and heating of the sample during the SDE process has been found to be one of the most efficient procedures for breaking down the matrix structure allowing steam distillation of the analytes. Furthermore, this acid treatment allowed a simultaneous clean up of the final extract as the matrix components form more polar products, which can then be easily separated from the non-polar analytes. According to the published results, most samples submitted to this kind of treatment did not require any additional clean up. Filek *et al.* report good recoveries for the SDE of OCPs from dairy products when using this type of acid pre-treatment: in the range 83–126% for powdered milk and human milk spiked at the 20.0–51.3 ng g^{-1} level, and in the range of 73–111% for a certified dairy product (OCP levels ranging from 1.5 to 6.6 ng g^{-1}). However, the SDE method failed when it was used for the extraction of the endogenous PCBs from dairy products with different fat contents. According to the reference method, the PCBs detected by Ramos *et al.*, in 1998 ranged from 2 to 0.01 ng g^{-1} in the investigated matrices. Nevertheless, most of the PCB congeners were found to be non-detectable with the SDE procedure and, when found at quantifiable levels, the reported concentrations were less than 26% of those determined by the reference method.

Rather similar results were reported by Seidel and Lindner in 1993 for the analysis of the OCPs in dairy products and human milk as none of the investigated compounds were found to be at a quantifiable level. However, no additional comparison with a reference method was included in this study, in which 10 g of sample was blended with water and ethanol. In this case, the alcohol, added as a co-distillation solvent, would also be able to disrupt the fat globule thereby allowing the SDE of the analytes. An important shortcoming of this kind of approach is the formation of large oil drops during the extraction, which increase the diffusion layer and hinder the SDE process. Filek *et al.* proposed blending of the sample with surfactants has been proposed as a possible solution for the case of fatty matrices without natural emulsifiers.

When no pre-treatment of the fatty sample was carried out, a co-distillation (total, according to Yoon *et al.*, or partial, according to Ramos *et al.*) of the lipids with the less volatile compounds occurred. Then, a post-treatment for isolation of the target compounds from the co-extracted matrix components was required. Following the implication of these results, it is rather surprising that neither pre- nor post-treatment of the sample was included

Table 3 SDE methods for the analysis of less volatile organic pollutants in fatty environmental samples (symbols as in Table 1)

^aDDT + DDE + TDE.

in some of the first reported applications of SDE for the analysis of toxic aromatic compounds in biological matrices. The investigated samples included fish tissues, muscle, liver and kidney and, although satisfactory recoveries (67–100%) were reported for the spiked PCBs, PCNs and Σ DDT (i.e. DDT + DDE + TDE), it is important to note that the spiking level in these experiments ranged from 1000–5000 ng g⁻¹ (Table 3). Even at such a high level of concentration, the authors reported an evident dependence of SDE recoveries on the analyte concentration. In fact, Cooke *et al.* found that the PCB, PCN and Σ DDT recoveries from animal tissues decreased from 67–100% to 65–85% when the spiking level decreased from 5000 to 1000 ng g⁻¹. According to this trend, it can be concluded that the very low levels of the endogenous pollutants in environmental samples together with the typical complexity of the matrix would be the main reasons for the disappointing results reported for some SDE applications involving non-spiked fatty samples.

Supercritical Fluids

It is now 170 years since Baron Charles Cagniard de la Tour discovered that, above a certain temperature, single substances do not condense or evaporate, but exist only as fluids. In the following decades the 'critical point' was characterized, with its parameters: the critical temperature and pressure. In recent years fluids have been widely exploited at conditions above, but not too far removed from, their critical temperatures and pressures. The term 'supercritical fluids' has been coined to describe these media. Their value lies in the fact that they can have properties intermediate between those we associate with gases and liquids, and also that the properties can be controlled by pressure as well as temperature. Consequently, supercritical fluids can often provide optimum conditions for both experiments and processes. Equally important, especially as regulations become tougher, is that supercritical fluids offer environmental advantages. This is mainly because carbon dioxide and water are available as solvents. The disadvantages of supercritical fluids are that high pressures and sometimes temperatures are involved, and, in the case of water, there are corrosion problems. As the technology to overcome them is available, these disadvantages become cost and convenience factors to weigh against potential advantages. Consequently, supercritical fluids are being exploited in specialized areas. Amongst these is supercritical fluid extraction (SFE), on both an industrial and analytical scale.

Substances used as supercritical fluids include hydrocarbons, such as propane and ethene, water and ammonia, fluorinated hydrocarbons and even xenon. However, one compound, carbon dioxide, has so far been the most widely used in extraction, because of its convenient critical temperature, cheapness, chemical stability, non-flammability, stability in radioactive applications and non-toxicity. Large amounts of carbon dioxide released accidentally could constitute a working hazard, given its tendency to blanket the ground, but hazard detectors are available. It is an environmentally friendly substitute for other organic solvents. The carbon dioxide that is used is obtained in large quantities as a by-product of fermentation, combustion and ammonia synthesis and would be released into the atmosphere sooner rather than later, if it were not used as a supercritical fluid. Its polar

character as a solvent is intermediate between a truly non-polar solvent such as hexane and weakly polar solvents. Because the molecule is non-polar it is often classified as a non-polar solvent, but it has some limited affinity with polar solutes because of its large molecular quadrupole. It has a particular affinity for fluorinated compounds and is useful for working with fluorinated metal complexes and fluoropolymers.

To increase the affinity of carbon dioxide to a variety of solutes, substances are added as 'modifiers' or 'entrainers'. The characteristics they impart include increased or decreased polarity, aromaticity, chirality, and the ability to further complex metal-organic compounds. For example, methanol is added to increase polarity, aliphatic hydrocarbons to decrease it, toluene to impart aromaticity, [R]-2-butanol to add chirality, and tributyl phosphate to enhance the solvation of metal complexes. They are often added in 5% or 10% amounts by volume, but sometimes much more, say 50%. They can have significant effects when added in small quantities and in these cases it may be the effect on surface processes rather than solvent character which is important. For example, the modifier may be effective in extraction by adsorbing onto surface sites, preventing the readsorption of a compound being extracted.

Because supercritical fluids have properties intermediate between those of gases and liquids to an extent controlled by pressure, optimum conditions can be sought for extraction. The medium can be adjusted for compounds to be sufficiently soluble to be removed, while at the same time the viscosity and diffusion coefficients can be high enough to bring about relatively rapid mass transport. **Table 1** shows typical values for the density and viscosity of a gas, supercritical fluid and liquid, taking carbon dioxide as an example. Density is more than half that of the liquid, giving rise to reasonable solubility. Moreover, by controlling the solvent density SFE can, to some extent, be made selective. In contrast, however, the viscosity of a supercritical fluid is much closer to that of a gas than that of a liquid. Thus pressure drop through a supercritical extraction cell is less than for the equivalent liquid process. Diffusion coefficients, also shown in Table 1 for naphthalene in carbon dioxide, are higher in a supercritical fluid than in a liquid. They are approximately inversely related to the fluid density. The advantage shown in the table is seen not to be so great and the main diffusional advantage lies in the fact that typical supercritical solvents have smaller molecules than typical liquid solvents. The diffusion coefficient for naphthalene in

Table 1 The density, ρ , and viscosity, η , of carbon dioxide and the diffusion coefficient for naphthalene in carbon dioxide, D , under gas, supercritical and liquid conditions

	$\rho/\text{kg m}^{-3}$	$\eta/\mu\text{Pa s}$	$D/\text{m}^2 \text{s}^{-1}$
Gas, 313 K, 1 bar	2	16	5.1×10^{-6}
Supercritical, 313 K, 100 bar	632	17	1.4×10^{-8}
Liquid, 300 K, 500 bar	1029	133	8.7×10^{-9}

a typical liquid would be closer to $1 \times 10^{-9} \text{ m}^2 \text{s}^{-1}$. Thus diffusion coefficients in supercritical fluid experiments and processes are typically an order of magnitude higher than in a liquid medium. This has the advantage of faster transport in the narrow passages typical in an extraction.

Application to Extraction

Because of the properties of a supercritical fluid, as described above, SFE can be more rapid than liquid extraction. Furthermore, the solvent is removed more easily, and fractionation of the extract by reducing the pressure in stages is feasible. SFE was first exploited on a process scale and this application continues to develop. On an industrial scale the first and most famous example is the 'natural' decaffeination of green coffee beans by the Hag process initiated in Bremen. Hops are also extracted by SFE on a large scale. Apart from these large-scale processes, more than 30 high-value oils, flavours and essences are extracted commercially in batch processes.

SFE is also used in chemical analysis to replace liquid extraction for sample preparation for a wide range of systems. SFE is now being used for the Total Diet Study programme of the US Food and Drug Administration. Usually, SFE is more rapid, less laborious and involves solvents which are less hazardous. Efforts still have to be made to make it more quantitative, but in fairness to SFE, extraction is often incomplete using a liquid. SFE is sometimes used on-line with an analytical method such as gas chromatography; it is most successful for some polymer and plant extractions. Table 2 summarizes the principle analytical applications of SFE.

Laboratory-Scale SFE

SFE is carried out on a laboratory scale for both sample preparation and for initial studies on possible industrial processes. A range of commercial equipment is available to carry out experimental studies

conveniently. A simple system is shown schematically in Figure 1. It can be assembled in-house and shows the principles involved. The fluid, typically carbon dioxide, is supplied from a cylinder with a dip tube to a pump, which can be a pump designed for liquid chromatography capable of delivering up to 5 mL per minute at a pressure of 400 bar and displaying the pressure and the flow rate. The pump head must be accessible so that it can be cooled by circulating an ethylene glycol and water mixture from a cooler, so that the fluid substance is pumped as a liquid. An alternative method of ensuring this is to use a fluid supply with an overhead pressure of around 100 bar of helium. In this case, cooling the pump head is not necessary, but the fluid will contain a small percentage of helium. The pumped fluid substance then passes into a controlled heater, which can be an oven for gas chromatography. It first passes through a length (typically 0.3 m) of stainless steel tubing into an extraction cell, rated for 400 bar at 100°C, which is fitted with a frit at the exit end (often both ends) to keep the sample matrix to be extracted in place. The exit tube is then connected to a restrictor to maintain the pressure in the system. This can be of stainless steel or, alternatively, a quartz capillary, in which case the connector will have a graphitized ferrule. The effluent then passes through a collecting solvent to trap the extracted compounds. Because of the cooling effect as the fluid expands to atmospheric pressure, it is usually necessary to heat the restrictor and the simplest way of doing this is with a domestic hair dryer. Evaporation of the collecting solvent may occur and it will be necessary to add solvent to the vial during the extraction. This simple device, although often satisfactory, can suffer from blocking of the

Table 2 Examples of the use of SFE in analytical sample preparation

Matrix	Examples of analytes extracted
Soils, sludges, water	Agrochemicals, polychlorobiphenyls, polycyclic aromatic hydrocarbons, fuel hydrocarbons, phenols, surfactants, metals
Food and animal tissue	Veterinary drugs, pesticides, anabolic steroids, mycotoxins, fats
Human milk and serum	Drugs
Polymers, food packaging	Low oligomers, polymer additives
Herbs, cosmetic products	Flavours, fragrances
Plant tissue	Alkaloids, various natural products, triglycerides
Fly ash, engine emissions	Polycyclic aromatic hydrocarbons, dioxins
Sedimentary rocks	Biomarker hydrocarbons
Fermentation broths	Biologically active compounds

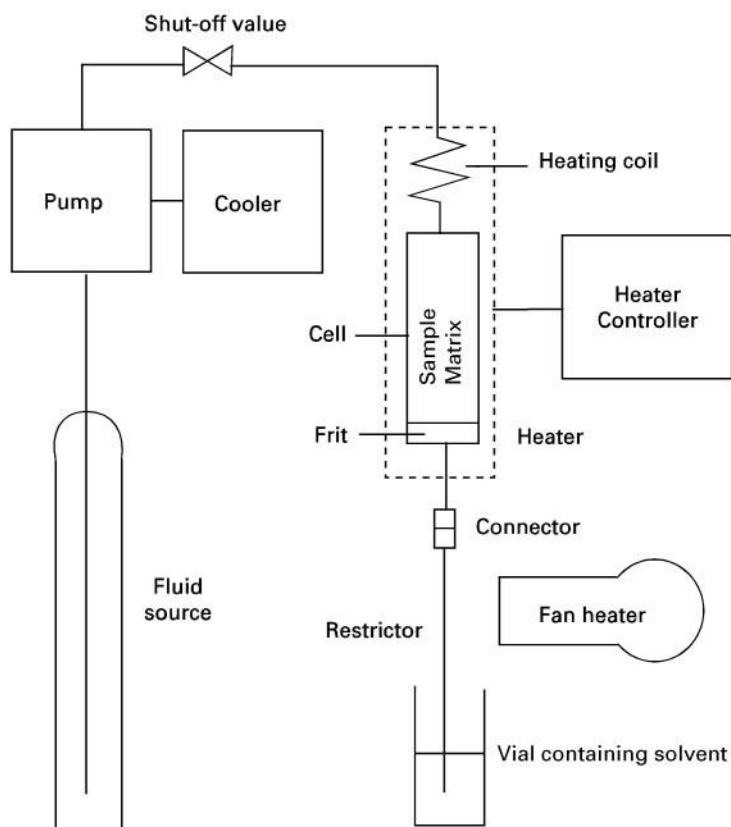

Figure 1 Schematic diagram of a simple system for carrying out SFE on a laboratory scale.

restrictor and loss of extracted compounds because of inefficient trapping. Furthermore, it does not allow independent control of the flow rate and pressure. More sophisticated commercial methods of pressure control and trapping are available.

In a representative experiment, a 1 mL cell is loaded with 0.5 g of the material to be extracted, (previously dried and ground to particles of 0.1 mm diameter). Carbon dioxide is pumped at a rate of 0.5 mL min^{-1} , measured as liquid at the pump. The temperature is 50°C and the pressure of 400 bar is maintained by a restrictor of $25 \mu\text{m}$ internal diameter and 12 cm length. The effluent is trapped in 3 mL of dichloromethane, ready for analysis by gas chromatography after an internal standard had been added. The extraction is carried out for 30 min. However, conditions for SFE vary widely and the details for a particular application can be found in the many reports now in the literature.

If a modifier is required, a second liquid pump must be added to the system and the output liquid fed into a mixing chamber just before the shut-off valve in Figure 1. Modifiers are usually added in relatively small amounts, say 5% or 10% by volume. It is possible to purchase cylinders of carbon dioxide al-

ready containing small amounts of common modifiers, such as methanol or acetone. If a modifier is used, the trapping solvent is conveniently the same as the modifier, as modifier will precipitate in the collection vial. Trapping is usually more efficient if a modifier is used.

The experiment described above is described as dynamic extraction, as the fluid is continuously flowing through the cell. Static extraction can also be carried out in a similar system if a second shut-off valve is inserted after the extraction cell. During an experiment, the cell is pressurized with fluid and the cell isolated so that contact between the matrix and fluid can occur for a period of about 30 minutes. A short dynamic stage is then carried out to remove the fluid, containing the dissolved extract, from the cell. For a static extraction, a modifier may be added as liquid to the cell before closing it.

SFE can readily be coupled to gas chromatography by passing the restrictor through a septum into the injection port of a chromatograph. This procedure can be much more sensitive, as all the extracted material is transferred to the chromatograph, whereas in an off-line experiment, only a small fraction of the collection solvent will be injected. Thus the procedure

is applicable for example to the analysis of pesticides at low levels. To carry out this procedure, the first section of the chromatographic column is cooled and the carrier gas turned off. SFE is then carried out with the carbon dioxide, or other fluid substance, passing out through the column and the extracted materials depositing at the inlet of the column. SFE is then stopped and the carrier gas passed through the column to flush out the carbon dioxide. The column is then raised to the analysis temperature and chromatography carried out.

Pilot and Process-Scale SFE

The basic process of extraction on a process scale is analogous to that on a laboratory scale and is shown schematically in **Figure 2**. The fluid substance, such as carbon dioxide, is pumped as a liquid and therefore is initially cooled to, say, 5°C, which must allow for some heating during pumping, and kept in a cooled reservoir. A system for adding a proportion of liquid modifier, not shown, may be incorporated. The fluid is then heated to the extraction temperature and pumped into an extraction cell, which is maintained at this temperature. The matrix to be extracted is packed into the extraction cell in a mesh basket to prevent it being carried out of the cell during extraction. Following extraction, the pressure is reduced to precipitate the extract through a control valve. The flow rate of fluid is controlled by the rate of pumping and the pressure in the extraction cell is controlled by the setting of the control valve for a particular pumping rate. Control systems may be used to control the extraction conditions. Reduction of pressure causes cooling of the fluid and so heat input is required, as shown. The precipitated material is collected at the base of the collection vessel, which has temperature control and also pressure control from the control valve on the fluid exit. A series of collection vessels at successively lower pressures may be employed to trap all the extract and separate it into fractions to some extent. A trapping liquid, such as a vegetable oil, may be used on a process scale to give a particular product. Trapping onto a surface, such as active charcoal, may also be used, particularly for volatile products, followed by thermal desorption. On a process scale the fluid leaving the collection vessel is likely to be cooled for recycling.

Mechanisms and Kinetics of SFE

Although extraction is essentially a complex process in which many factors, including procedural parameters, are involved, in a basic theoretical approach

the process of extraction can be considered to involve the three factors shown in the SFE triangle below.

The solute must, firstly, be sufficiently soluble in the supercritical fluid to be removed by solution in the fluid flow. If this is not the case, it will be revealed by interpretation of the kinetic recovery curve, as shown below. If solubility is insufficient, the situation may be improved by adding a modifier to the fluid, as described earlier.

Secondly, the solute must be transported sufficiently rapidly, by diffusion or otherwise, from the interior of the matrix in which it is contained. The diffusion process may be normal diffusion of the solute, or it may involve diffusion in the fluid thorough pores in the matrix. The time-scale for diffusion will depend on the diffusion coefficient and the shape and dimensions of the matrix or matrix particles. Of these the shortest dimension is of great importance, as the times depend on the square of its value. Values for this quantity of 1 mm or preferably less are usually necessary.

Thirdly, the solute must be released by the matrix. This last process may involve desorption from a matrix site, passage through a cell wall, or escape from a cage formed by polymer chains. It can be slow and in some cases it appears that part of the substance being extracted is locked into the structure of the matrix. An example is the SFE of additives and lower oligomers from polymers, which can give much lower results than obtained by dissolving the polymer in a solvent, or using liquid extraction at higher temperatures, which swells the polymer to a greater extent. Thus SFE will not always give the total amount of a compound in a sample, only the amount extractable under particular SFE conditions. It may be that the latter is of interest, for example for determination of the migration of additives from polymers into food-stuffs, but if the total amounts are required, SFE may not be applicable. Preliminary experiments, and comparisons with other methods, are necessary. It can be strongly temperature-dependent and thus higher temperatures may improve the situation. The addition of modifiers may often reduce the matrix effect; in fact modifiers are often more important in this respect

Figure 2 Schematic diagram of SFE on a process scale.

than in enhancing solubility. The mechanism is thought to involve interactions with surfaces. It should be emphasized here that the matrix effect also occurs with liquid solvent extraction. The fact that solvent strength can be varied in a supercritical fluid means that the matrix effect is more obvious in this medium and can be studied in more detail. The advantage is that conditions can often be found in SFE where the matrix effect is minimized.

A related problem is the presence of water. Water is not very soluble in many fluids, such as carbon dioxide, and it can 'mask' the substances to be recovered. The rate of extraction may sometimes be equal to the rate of water removal. It may be necessary to dry the material to be extracted in air or by admixture with

a drying agent, such as diatomaceous earth or anhydrous magnesium sulfate. Reduction of the water content of plant material from, say, 80% (as measured by mass loss at 100°C) down to 10% may be desirable, provided valuable volatiles are not lost in the process. However, water may assist extraction by acting as a modifier, as is believed to be the case for coffee decaffeination.

Modifiers or entrainers added to the fluid, as discussed earlier, may be beneficial to any of the above factors. They may improve the solubility of the compounds to be extracted and this was originally thought to be their most important role. However they often improve diffusion by absorption into a polymer and swelling it, for example. Modifiers

Figure 3 Examples of schematic recovery curves, where recovery is controlled by (A) diffusion; (B) diffusion and matrix effects; and (C) by solubility.

Figure 4 Extraction of lycopene from tomato paste at 100°C and 400 bar at two flow rates plotted against the volume of CO₂ passed.

may improve the matrix factor by adsorbing on surface sites. Modifiers, such as methanol, can reduce the water problem by improving its solubility in the fluid.

Figure 3 shows examples of the types of curves of recovery versus time that can be obtained in SFE. Curve (A) is a typical curve obtained when the process is controlled by diffusion. When matrix effects are significant, the results may have the form of (B). Curve (C) is an example of recovery behaviour when the extracted compound is not very soluble in the extracted fluid. It is thus highly desirable, when developing a procedure for a particular application, to carry out kinetic experiments to obtain curves of recovery versus time. The curves can then be used to investigate the reaction mechanism, as well as determine a suitable extraction time. These developments are detailed in some of the books listed in the bibliography. Kinetic experiments are done by replacing the collection vial periodically. As extraction is faster initially, the time intervals are smaller near the beginning of an extraction. A representative series of times for changing over the collection vial is 2, 5, 10, 20, 30, 40 and 60 min. The total amount extracted can also be compared with liquid extraction.

An example of an experimental recovery curve is now given in Figure 4 for the extraction of lycopene from 0.5 g of tomato paste, dried by mixing with diatomaceous earth, at 100°C and 400 bar. Flow rates of 2 mL min⁻¹ and 3 mL min⁻¹ per minute (measured as liquid at the pump) were used, and the results plotted not against time, but against the volume of CO₂ passed (i.e. the time multiplied by the flow rate). The fact that the two curves approx-

imately coincide, indicates that the extraction is principally by the partition of lycopene between CO₂ and the tomato paste matrix, which in turn is related to the solubility of lycopene in CO₂.

Conclusions

Supercritical fluid extraction can be a clean alternative to liquid solvent extraction both for analytical sample preparation and for production scale, because environmentally friendly solvents such as carbon dioxide can be used instead of organic solvents. Some applications are found to be more successful than others. It requires more expensive equipment and a greater commitment to process development than liquid extraction. Nevertheless, it is being applied in specific areas, such as for polymer additives in analytical chemistry and as a method for obtaining valuable compounds from plants on a process scale.

Ultrasound Extractions

Introduction

Sound is transmitted through a medium by inducing vibrational motion of the molecules forming part of it. Human hearing threshold is reached when the frequency of sound is higher than 16–18 kHz. Ultrasound comprises the region of frequencies between 18 kHz and 100 MHz, the upper limit not being sharply defined (Figure 1). This broad region can still be divided into two different regions: power ultrasound between 20 and 100 kHz and diagnostic ultrasound between 1 and 10 MHz. The above classification relies on the capability of energy transmission into the medium at the lower frequencies, which induces the cavitation phenomenon.

Relevant applications of ultrasonic energy include its use in animal communications (e.g. bat navigation and dog whistles), medicine for fetal imaging, underwater range finding (SONAR) and nondestructive testing for metal flaws. Recently, ultrasound has also been considered a potential source for enhancement of chemical reactivity. A large variety of chemical and industrial processes rely on high intensity ultrasonica-

tion, e.g., cleaning, drilling, soldering, acceleration of chemical reactions, emulsification, sterilization, flotation, homogenization, dissolution, deaggregation of powder, disruption of biological cells, extraction, crystallization, oxidation, etc. A further advantage of the above-mentioned ultrasound-assisted processes is the relative simplicity of both method development and instrumentation.

A brief description of ultrasound fundamentals as well as a discussion of its applications for solid-liquid extraction is given below.

Fundamental Features of Ultrasound

Vibrations Induced by Ultrasound

Sound waves are usually represented as a series of vertical lines, with intensity being related to separation between them, or as a sine wave where intensity is related to the amplitude (Figure 2).

Ultrasonic irradiation of a liquid medium gives rise to an acoustic pressure (P_a) which is added to the hydrostatic pressure (P_h) which exists in the medium. The acoustic pressure depends on time according to the following expression:

$$P_a = P_A \sin 2\pi ft$$

where f is the frequency of the wave (> 16 kHz), t is the time and P_A is the maximum pressure amplitude of the wave. At the point where the lines are close to each other, pressure is higher than normal (i.e. compression region), whereas at the point where the lines are furthest apart, pressure is lower than normal (i.e. rarefaction region).

The intensity of the wave can be defined as the energy transmitted per second per cm² of fluid and can be related to P_A as follows:

$$I = P_A^2(2\rho c)^{-1}$$

Figure 1 Sound frequencies (Hz, cycles per second). ■, human hearing 16 Hz–16 kHz; ▨, power 20 kHz–100 kHz (clearing plastic welding sonochemistry); ■, high frequency 1 MHz–10 MHz (medical diagnosis, chemical analysis). (From Mason TJ (1991).)

Figure 2 Sound motion in a liquid medium.

where c is the velocity of sound in the medium and ρ is the density of the medium.

Attenuation of Sound in a Liquid Medium

The intensity of the ultrasonic wave decreases with increasing penetration into the medium. Molecular vibration induced by the sound wave results in loss of intensity of the wave, which is transformed into heat. Heating occurs in the sites of compression and cooling at the sites of rarefaction. Since the compressibility of liquids is small, there is little heating caused by ultrasound as waves pass through the medium. The heating effect is caused by the degradation of acoustic energy due to absorption, following the equation:

$$I = I_0 \exp(-2\alpha d)$$

where I is the intensity at distance d from the ultrasound source and α is the absorption coefficient.

The Phenomenon of Cavitation

The pressure wave caused by ultrasound transmitted in a liquid medium will, in turn, cause an oscillation of the molecules around their mean position. When a large negative pressure (P_c) is applied to the liquid, where P_c (rarefaction pressure) = $P_a - P_h$, the distance between molecules can overcome a critical distance R , under which the liquid breaks down so that cavitation bubbles form. The R distance for water is

around 10^{-8} cm and the pressure involved is 10.1×10^5 kPa, where $P_c = 2\sigma/R$, σ is the surface tension. The cavitation process can be observed at much lower negative pressure (e.g. 10.1×10^4 kPa), as a result of the presence of gas nuclei as dissolved gas, suspended gas bubbles, or gas bubbles caused by heat fluctuations within the liquid. The cavitation threshold decreases with degassed liquids or as consequence of the increase in hydrostatic pressure.

Cavitation can be divided into two classes: transient and stable. Stable cavities oscillate around some equilibrium size (R_0) over several rarefaction-compression cycles. In contrast, transient cavities usually exist over one acoustic cycle, increasing their size during the cycle and collapsing into smaller bubbles. The time required for a bubble to collapse is usually shorter than the period of the acoustic wave, and therefore P_m (i.e. pressure in the liquid at the moment of transient collapse, $P_m = P_h + P_a$) can be considered as constant during collapse. This time can be expressed as:

$$t = 0.915 R_m (\rho/P_m)^{1/2}$$

where R_m is the radius of the cavity at the moment of collapse.

Temperatures and pressures reached inside a cavitation bubble containing nitrogen in water at ambient temperature and pressure before collapsing are nearly 4200 K and 975 bar, respectively. The high temperature existing inside cavitation bubbles accounts for radical formation, whereas the shock wave caused by bubble implosion may be responsible for the increased chemical reactivity.

Influence of Different Parameters on the Cavitation Process

The different processes occurring during cavitation (i.e. nucleation, bubble growth and collapse) can be affected by parameters such as liquid medium, intensity and hydrostatic pressure, which are among the most important.

Thus, the formation of cavitation bubbles decreases on increasing ultrasonic frequency. This is due to insufficient time for the rarefaction cycle to allow the growth of the bubble so that disruption of the liquid can be produced.

As expected, cavitation is decreased in viscous media as a result of the increased negative pressure in the rarefaction region needed for disruption of the liquid.

The number of nuclei for cavitation depends on temperature. An increase of temperature from -10 to $+50^\circ\text{C}$ causes an increase in sonochemical effects as a result of the increased cavitation. Nevertheless,

when temperature exceeds 50°C the decrease in surface tension and increase in vapour pressure within the cavity will result in a lower P_{\max} and, consequently, sonochemical effects will diminish.

The increase in gas content within the liquid leads to a lower cavitation threshold and intensity of the shock wave released on the collapse of the bubble. It has been observed that the use of monoatomic gases (He, Ar, Ne) provides more effective cavitation than diatomic gases (N_2 , O_2 , air).

External pressure also influences the cavitation process. Thus, when the external pressure is increased (P_h), a lower cavitation threshold and intensity of cavitation collapse are observed. When $P_h - P_a > 0$, it means that the negative phase of the sound will no longer exist, hence eliminating cavitation.

Finally, another factor that can influence cavitation is intensity, which enhances cavitation.

Effect of Power Ultrasound on Chemical Systems

Homogeneous Medium

Mechanical and chemical effects caused by cavitation fall into three different processes (Figure 3). First, the cavitation bubble contains solvent vapour which is subject to high temperatures and pressures on collapsing. This promotes the formation of reactive species, e.g. radicals. For example, when water is used as solvent the following reactions take place:

Second, surface-active reagents can accumulate at the interface between the bubble and the bulk liquid. Finally, in the surrounding of the bubble, an intense shock wave will be produced causing enormous shear forces.

Figure 3 Cavitation effects in a homogeneous liquid.

Heterogeneous Medium

In this case, there are two types of cavitation collapse that can affect the surface of solids (Figure 4): (1) cavitation collapse on the surface of the solid due to the presence of surface defects,

Figure 4 Cavitation effects at a solid-liquid interface: (A) cavitation collapse on the surface of a solid particle; (B) cavitation collapse close to a surface of a solid particle.

entrapped gases or impurities; (2) cavitation collapse close to a surface causing a microstreaming of solvent to impinge on the surface (i.e. cleaning action of ultrasound). It has been observed that ultrasonic irradiation can cause particle rupture (i.e. disruption) which results in a decrease in particle size and an increase in surface area for reaction. Alternatively, cavitation collapse in a medium containing two immiscible liquids can cause the formation of an emulsion.

Instrumentation

Among the several types of sonicator systems currently available, mostly bath and probe-type sonicators are used. Both systems are based on an electromagnetic transducer (i.e. device capable of converting mechanical or electrical energy into high frequency sound) as a source of ultrasound power, commonly operating at a fixed frequency of 20 kHz.

Ultrasonic sources used now rely on the piezoelectric effect discovered by Curie (1880). Ultrasonic processors implement transducers which are based on the changes in dimension of some materials on application of an electrical potential across opposite faces. When the potential is modulated at high frequency, the material converts the electrical energy into mechanical energy (sound). A sufficiently high alternating potential will result in the generation of ultrasound. The first ultrasonic transducer was reported by Galton in 1883, who tried to establish the threshold frequency of human hearing.

Bath Systems

In these systems the transducer is usually placed below a stainless steel tank, the base of which is the source of ultrasound (Figure 5). Some tanks are also provided with a thermostatically controlled heater. Typically, the ultrasound power levels delivered by

Figure 5 Schematic diagram of an ultrasonic bath.

most commercial ultrasonic baths (e.g., 1–5 W cm⁻²) are sufficient for cleaning, degassing of solvents and extraction of adsorbed metals and organic pollutants from environmental samples, but are less effective for extraction of analytes bound to the matrix. The power should be great enough to cause cavitation within the extraction vessel placed inside the bath; this is not always achieved with commercial ultrasonic baths.

An important factor influencing extraction efficiency is the position of the extraction vessel inside the bath. For a bath with a single transducer on the base, the extraction vessel must be located just above the transducer, since power delivery will be a maximum at this position. In order to obtain reproducible results, the bath must be either thermostatted or preheated at the equilibrium temperature (i.e. maximum temperature measured in the liquid under continuous running conditions) since most cleaning baths warm up slowly during operation. An important drawback of most cleaning baths is the lack of power adjustment control.

Probe Systems

Probe-type sonicators are able to deliver to the extraction medium up to 100-fold greater power than that of an ultrasonic bath, so that a better performance is expected. One main feature for the successful application of ultrasonic probes for many chemical processes is that the ultrasonic energy is not transferred through the liquid medium to the extraction vessel but introduced directly into the system (Figure 6). The ultrasonic probe consists of the following components:

- A generator which is the source of alternating electrical frequency (typically 20 kHz). The generator allows tuning to be carried out for optimum performance.

Figure 6 Schematic diagram of a probe-type sonicator.

- Ability of the ultrasonic processor to be used in pulsed mode operation which allows the medium to cool between pulses of sonication.
- The upper horn element – a piece of titanium to which the detachable horn is attached, forming both the emitter or booster.
- A detachable horn, usually made of a titanium alloy, which allows the vibration of the fixed horn to be transmitted to a chemical system. Tip erosion can occur as a result of cavitation. Depending on the volume of sample to be irradiated a range of detachable horns can be used.

Despite the improved performance displayed by probe-type sonicators for solid-liquid extraction compared with cleaning baths, a series of problems can arise with the use of these sonicators. Volatile components can be lost due to the 'degassing' effect of the ultrasound power. Ultrasound irradiation by means of probes is accompanied by a large amount of heat generated during operation, hence some cooling of the sonication vessel is required.

Ultrasound-Assisted Extraction

Extraction techniques are widely accepted as a prerequisite for analytical determination of both organic and inorganic analytes in a large variety of samples.

As a part of an analytical process, sample preparation is considered to be an essential step so that the entire process can be simplified. In this case, the ability of many analytical systems to handle liquid samples has brought about the development of separation methods which fulfil a main objective, i.e. to obtain quantitative analyte leaching from the solid matrix using a suitable solvent, with little or no matrix release, so that matrix effects can be kept to a minimum during the measurement steps. For speciation applications, a last condition of a solid-liquid extraction method must be the maintenance of the species integrity during treatment.

Table 1 shows the most relevant methods for treatment of solid samples based on analyte extraction. An important requirement of most techniques shown is that solvents at high temperature (i.e. at boiling point) or pressure must be used. In contrast, operation with ultrasonic processors can be performed at ambient temperature and normal pressure, and mild chemical conditions can be used in most cases.

Sonication is usually recommended for pretreatment of solid environmental samples for the extraction of nonvolatile and semivolatile organic com-

pounds from solid, such as soils, sludges and wastes. When comparing the different methods available for analyte extraction from solid samples, sonication is considered as an effective method since unsophisticated instrumentation is required and solid-liquid separations can usually be performed in a short time using diluted reagents and low temperatures. To date, most of applications of ultrasonic extraction have been carried out for organic compounds, but the usefulness of ultrasound for element extraction is still to be explored. Some examples of solid-liquid extraction of some elements with the use of ultrasound are shown in Table 2. It should be pointed out that for many applications reported in this table, operation conditions were intended to obtain a homogeneous slurry so that a representative aliquot could be sampled; specific optimization of the variables influencing ultrasound-assisted extraction processes was not performed. Significant variables influencing the solid-liquid extraction process with a probe-type sonicator are sonication time, vibrational amplitude of the probe, acid concentration, particle size and solid concentration in the liquid. In general, the presence of an acidic liquid is an important prerequisite for quantitative extraction to be achieved; nitric acid at low concentration (e.g. 3–5% v/v) is usually chosen for extraction of elements from solid samples.

Quantitative extraction can be achieved for some analytes such as As, Cu, Pb, Cd, etc., from plant and animal tissues. Nevertheless, incomplete extraction has been observed from samples containing a typical inorganic matrix (e.g. sediment). It is believed that this finding is related to the ability of ultrasound to penetrate the solid material. A further variable that influences the solid-liquid extraction is the analyte-matrix interaction. Thus, strongly bound analytes should be more difficult to extract, thereby requiring more stringent extraction conditions. A relationship between extractability and binding characteristics of elements in the sample is yet to be established.

The extraction efficiency obtained with ultrasound could be increased by addition of glass beads which promote particle disruption by focusing the energy released by cavitation, and by physical crushing. Particle disruption could also be enhanced by increasing hydrostatic pressure and viscosity. The use of a bubbling gas during sonication gives rise to an enhanced formation of H_2O_2 and hydroxyl radicals ($\text{OH}\cdot$) thus aiding analyte extraction from oxidizable materials. In general, the use of probe-type sonicators at the appropriate vibrational amplitude and sonication time is required so that extraction efficiency can be improved for strongly-bound elements.

Table 1 Extraction methods from solid samples.

<i>Sample pretreatment method</i>	<i>Principles of the technique</i>
Accelerated solvent	Sample is placed in a sealed container and heated to a temperature higher than its boiling point, causing pressure in the vessel to rise.
Automated Soxhlet	A combination of hot solvent leaching and Soxhlet extraction; sample in thimble is first immersed in boiling solvent and then the thimble is raised for Soxhlet extraction with solvent refluxing.
Forced-flow leaching	Sample is placed in a flow-through tube, and solvent is pumped or pushed through high-pressure nitrogen gas, while the tube is heated near the boiling point of solvent.
Gas phase	After equilibrium, analytes partition themselves between a gas phase and the solid phase at a constant ratio; with static headspace extraction, volatiles are sampled above the solid; with dynamic headspace extraction, volatiles are sampled by continuously purging the headspace above a sample with inert gas, trapping them on a solid medium, and then thermally desorbing them into a gas chromatograph.
Homogenization	Sample is placed in a blender, solvent is added, and sample is homogenized to a finely divided state; solvent is removed for further work-up.
Pervaporation	Volatile substances present in a heated donor phase placed inside a pervaporation module evaporate through a porous membrane and the vapour condenses on the surface of a cool acceptor stream on the other side of the membrane.
Solid-liquid extraction	Sample is shaken together with the appropriate solvent in a container and the liquid separated by filtration
Sonication	Finely divided sample in a container is immersed in ultrasonic bath with solvent and subjected to ultrasonic irradiation; an ultrasonic probe or cell disrupter can also be used.
Soxhlet extraction	Sample is placed in a disposable, porous container (thimble); constantly refluxing solvent flows through the thimble and leaches out analytes that are collected continuously.
Supercritical fluid	Sample is placed in flow-through container and a supercritical fluid (e.g. CO ₂) is passed through sample; after depressurization, extracted analyte is collected in solvent or trapped on adsorbent and desorbed by rinsing with solvent.
Thermal	A form of dynamic headspace analysis, but the sample is heated (controlled) to much higher temperatures (as high as 350°C).

Future Prospects

The use of ultrasound as a sample preparation method for solid-liquid extraction is widespread in many laboratories and can be regarded as fast and effective. Extractions based on sonication have been employed for the isolation of weakly-bound organic compounds from solid samples such as soils, animal tissue, plants, etc., and are comparable to methods involving more intensive treatments (e.g., Soxhlet, accelerated solvent, etc.). However, ultrasound applied to solid-liquid extraction of inorganic analytes has rarely been attempted, perhaps owing to the inefficient sonochemical effects caused by most ultrasonic baths, which are more extended than probe-type sonicators. Ultrasound irradiation from high-inten-

sity ultrasonic processors opens the door to new perspectives, mainly concerning those analytes that are strongly-bound to the matrix. Thus, extraction of elements from solid samples is feasible under optimized sonication conditions, hence avoiding the more intensive treatments commonly employed for matrix decomposition (i.e. dry or wet ashing procedures). New possibilities of ultrasound lie in its use as selective extraction techniques for metal speciation in conjunction with the appropriate leaching reagents. Thus, ultrasound-accelerated sequential extraction schemes for metal partitioning in environmental solid samples (e.g. soil, sediment, sewage sludge) or selective extraction of physicochemical forms of elements constitute new sample preparation strategies which deserve further research.

Table 2 Percentage of metal extracted into the liquid phase of slurries prepared in an acidic diluent and subsequently homogenized by sonication

Sample	Element and percentage of extraction	Sonication system	Reference
Bovine liver	Cd (111%)	Bath	1

FLOTATION

Bubble–Particle Adherence: Synergistic Effect of Reagents

B. J. Bradshaw and C. T. O'Connor, University of Cape Town, Rondebosch, South Africa

Copyright © 2000 Academic Press

Introduction

It is well known in the practice of flotation that mixtures of various collectors often behave with greater effectiveness than would be expected from their individual known characteristics. This phenomenon is a classical example of synergism in flotation, in which the combined effect exceeds the sum of the linearly weighted partial effects. Such phenomena are not only consciously applied by adding mixtures of reagents, especially collectors, but may also occur inadvertently since many industrial reagents are synthesized from less than absolutely pure chemicals, resulting in the presence of small amounts of different product molecules which are often capable of having a positive synergistic effect on the flotation behaviour. Such synergism can have a significant effect not only on the recovery but also on the selectivity of specific minerals in differential flotation. The manner in which reagents interact in order to achieve a synergistic effect is a complex function of their chemical nature as well as their chemisorptive or physisorptive properties. The former will determine whether the chemical composition of the reagent changes when another compound is present through, for example, a dimerization reaction. The latter will determine how competitive or synergistic adsorption will influence the ultimate flotation behaviour. The analysis of synergism between reagents in flotation is complicated by the fact that the roles and interactions of the different classes of reagents are difficult to isolate due to the complexity of the flotation process, viz. the frother is added to stabilize the froth zone but can also interact with the collector and affect the performance of the collection zone.

This review firstly discusses those properties of pure collectors, frothers, depressants and activators which are pertinent to their potential synergistic

behaviour. The interactions between collectors, frothers and each other are then reviewed. The emphasis here is on sulfide minerals but similar effects have been extensively reported in the case of oxide flotation. Finally, an hypothesis is proposed to explain the synergism observed when mixtures of thiol collectors are used in the flotation of pyrite. This represents a typical sulfide mineral flotation system and will serve to highlight how the various sub-processes of flotation may be influenced in a synergistic manner, thus influencing the ultimate flotation performance.

Functional Roles of Pure Reagents

Collectors

The predominant functional role of collectors is to induce hydrophobicity by adsorption onto the desired mineral and they are therefore concentrated at the mineral–water interface. Collectors are heteropolar molecules containing a nonpolar hydrocarbon chain, which renders the particle hydrophobic, and a polar group that interacts with the mineral surface.

Collector molecules can be divided into three classes: nonionic, which are largely insoluble and used in the flotation of coal and graphite; cationic, which are typically amine salts and used in the flotation of silicates and sulfides at alkaline conditions; and anionic, which are used to float basic minerals such as metal oxides and sulfides. Fatty acids are used for the flotation of nonsulfide minerals such as apatite, calcite, feldspar and hematite. Sulfonates and sulfates are used for apatite as their frothing properties limit their usefulness for other systems. Sulfhydryl or thiol collectors are used for the flotation of sulfide minerals and, of these, xanthates, first patented in 1925, are still the most widely used.

The mechanism of mineral–collector bonding depends on the collector type and the nature and charge of the mineral surface and can occur via physisorption or chemical bonding. There are several modes of chemical interaction of the collector with the mineral surface. In the case of physisorption, the collector does not interact with the mineral surface. The attachment is due primarily to van der Waals forces and the Gibbs free energy of adsorption is relatively low. In the case of chemisorption, when the collector interacts with the mineral surface without movement of the metal ions from their lattice sites, this produces

monolayer coverage. When the surface chemical reactions are associated with movement of metal ions from their lattice sites, multilayers may form. If a reaction occurs in the bulk solution between dissolved ions and the collector, a hydrophobic surface will only be established if there is bulk precipitation on the mineral surface.

Sulfide minerals are semiconductors and react electrochemically with thiol collectors according to the mixed potential model. This involves the cathodic reduction of oxygen and the anodic oxidation of collectors. The electrochemical potential of the system and the thermodynamics of the respective reactions determine the nature of the surface products. Depending on the nature of the surface products formed, the collector may however be physisorbed, such as in the case of the neutral dithiolate, or chemisorbed, as in the case of the metal thiolate. Naturally, when mixtures of collectors are used, a combination of these mechanisms and products may occur, possibly resulting in an enhanced flotation performance.

Frothers

Frothers are added to create a stable dispersion of bubbles in the pulp which will subsequently create a reasonably stable froth and which will allow selective drainage from the froth of entrained gangue and improve the flotation selectivity. The frother also affects the flotation kinetics. They are nonionic heteropolar molecules and, unlike collectors, are not associated with particular categories of minerals. The frothing ability of a compound is associated with hydroxyl ($-OH$), ester ($-COOR$) and carbonyl ($-CO$) chemical groups, and commercial frothers can be divided into three main categories: alcohols, alkoxyparaffins, polyglycols and polyglycol ethers. The polar end of the frother molecule forms hydrogen bonds with the water and no mineral-frother bonds are formed. The nonpolar end is hydrophobic so that the frother concentrates at the air-water interface and is thus described as being surface-active. This affects the surface tension, which indicates the difference between the surface activity of frothers and causes a stable froth to form. In general, increased surface activity results in increased floatability and froth stability.

Depressants

The role of depressants, which are either inorganic salts, such as sodium silicate, sodium sulfite or organic compounds such as polysaccharides, dextrin and starch derivatives, guar gums, carboxymethylcellulose and alginates, is to reduce the collection of

unwanted gangue which consists of typically talcaceous or other oxide minerals. This is done by either enhancing the hydrophilic nature of the gangue surface, by preventing the formation of hydrophobic species which might adsorb on the gangue surface or by preventing the coating of unwanted slimes on the mineral surface. Mechanisms of depression also include the formation of large aggregates and the complexation of the collector in solution.

Activators

Activators are specifically added to enhance flotation performance, usually by modifying the surface of the particle in some way so as to make it more amenable to interaction with the collector. They may however have unexpected effects, for example, by complexing with other ions in solution and rendering particles less floatable. Copper sulfate, for example, is a well-known activator. Under certain circumstances, in sulfide flotation, the copper may ion-exchange with surface ions, creating a readily floatable particle but in different pulp conditions may complex as a hydroxy species and depress the particles. Such effects may be considered synergistic but fall outside the scope of this article. Another commonly used activator is sodium sulfide or bisulfide which is used as a sulfidizing reagent for tarnished or oxidized ores.

Synergistic Interactions Between Reagents

There has been a considerable amount of work done on the effects of mixing reagents in flotation. Table 1 summarizes much of this literature with respect to type of reagents mixed, minerals tested, measurements made and the benefits observed.

Collector-Collector Interactions

The use of mixtures of collectors has long been recognized in plant practice and has been shown to enhance flotation performance. These benefits have been reported for a wide range of collector mixtures (anionic, cationic and nonionic) and include lower dosage requirements, improved selectivity and rates and extents of recovery and an increase in the recovery of coarse particles. In many cases an optimum ratio of constituent collectors was shown to exist. Dithiophosphates are a class of thiol collectors that are so widely used in mixtures that they are known as promoters.

Using measurements obtained from experimental techniques shown in Table 1, a number of mechanisms have been proposed by various authors to

Table 1 The effects of mixing reagents in Flotation

<i>Interactions</i>	<i>Reagents^a (ratios tested)^b</i>	<i>Mineral systems^c</i>	<i>Techniques</i>	<i>Benefit of mixture</i>	<i>Reference</i>
Collector: collector Thiol–thiol	Ethyl X: amyl X (2: 1, 1: 2 mass)	Arsenopyrite (P)	Batch flotation	Higher rates of recovery with mixtures. Optimum mixtures: ethyl X: amyl X (1: 2) for arsenopyrite and (1: 1) for galena	Plaskin <i>et al.</i> (1954)

explain the fact that the mixtures give a flotation performance greater than that expected from the contributions of each individual component. These proposals are based on effects related to adsorption of the collectors on the surface of the particle, interactions between the reagents, either in the bulk or at the surface, or changing froth characteristics.

When using mixtures of collectors it has often been observed that there is a greater surface coverage of the adsorbed collectors on the mineral than would have been expected from their weighted averages. This could either enhance the overall hydrophobicity of the mineral surface or result in an adsorbed surface layer of collector molecules more suitable for frother-collector interactions. The increased mineral hydrophobicity could result from the formation of a more evenly distributed surface species. The change in hydrophobicity can be measured by, for example, changes in contact angle, bubble loading and ultimately the recovery in batch flotation tests. It has also been proposed that, for certain systems, when a mixture of collectors is exposed sequentially to a surface

which, by definition, must have a heterogeneous distribution of energetically different sites, the weaker collector will adsorb preferentially on the strong sites and the strongly adsorbing collector, added subsequently, will adsorb on the weaker sites. In this way as many sites as possible are utilized for adsorption, thus enhancing the hydrophobicity. Single collector addition may only result in adsorption on strongly adsorbing sites, forming nonuniform coverage and thus a less than optimal adsorption capacity. It is possible that such an effect will not be observed if the collectors are pre-mixed before addition, thus emphasizing the fact that synergism may depend on the sequence of addition as much as on the presence of a mixture.

The grade of the concentrate is largely a function of the depressant used, which affects the froth zone characteristics. The presence of hydrophobic solids in the froth phase will destabilize the froth, causing bubble coalescence in the froth which results in improved drainage and consequently increased selectivity and grades. The presence of hydrophilic or only

Figure 1 The effect of mixtures of collectors on batch flotation performance of a low-grade pyrite ore at pH 4. Values measured (squares) were compared with those predicted from the linearly additive mole ratio contribution of potassium *n*-butyl xanthate (PNBX) and dithiocarbamate class of reagents (DTC; triangles) for (A) % sulfur recovery obtained for 25% grade; (B) % sulfur grade obtained for 80% recovery; and (C) water recovery obtained after 7 min (g).

slightly hydrophobic minerals can stabilize the froth zone and thereby decrease the grade achieved. The use of a combination of collectors resulting in both

physisorbed and chemisorbed surface products can also affect the froth structure and influence the final grade achieved. It is also often observed that

enhanced performance is achieved when a strong collector with no frothing properties is used with a weaker collector with frothing properties. The former increases coarse particle recovery and the latter increases fine particle recovery. This is however not a true synergistic effect since the combined effect is the sum of the individual effects.

Collector-Frother Interactions

Before the collision of a mineral particle and an air bubble, adsorbed layers of reagents are present at both interfaces. At the time of collision, there are interactions between these layers which are affected by the nature and charge of the respective molecules. Any associated molecules are anchored to the mineral group by the polar groups of the collector. The strength of this film determines the tenacity of attachment of the mineral to the bubble and the ultimate success of the flotation process. When the molecular associations between frother and collector are suitably balanced the appropriate mechanical properties of the film at the interface are created, resulting in good recoveries and grades. If the collector or frother dosages are too high, the molecules would be too densely packed and penetration and successful attachment would not take place. This supports the well-known phenomenon that too high a dosage of reagents can result in reduced recoveries. In this case synergistic interactions between the frother and collector that improved flotation performance at the lower dosages are no longer possible at the higher dosage.

Frother molecules can accumulate at the mineral surface, without enhancing its hydrophobicity and, at

the time of collision with a bubble, re-orientate quickly, facilitating mineral-bubble attachment. This produces a stable three-phase froth and strong tenacity of mineral-bubble attachment. An alternative explanation is that at the mineral-water interface the alkyl chains of frother and collector molecules are held together by van der Waals forces. Frothers are able to hydrogen-bond with the oxygen atom in the collector molecule. These associations are only formed when a mineral is present. The frother's ability to interact with the collector is thus more significant than its surface activity, which is required to produce a stable froth zone. This also explains why detergents are not suitable frothers. It has moreover often been shown that the collector can affect frothing properties and that the frother can affect mineral hydrophobicity.

The surface activity and thus frothability of the frother is very sensitive to the presence of small amounts of other substances, such as impurities or collector molecules. The chemical nature of certain combinations of frothers and collectors may result in interactions occurring at the point of collision of the pure components. The properties of frothers can sometimes be additive, with the mixing of stronger and weaker frothers to form medium-strength frothers.

Synergistic Interactions – A Case Study

Synergistic enhancement of flotation performance has been observed in batch flotation tests with a low

Figure 2 The mass loading per bubble for bubbles of average diameter of 1.2 mm of pyrite with equimolar amounts of potassium *n*-butyl xanthate (PNBX), dithiocarbamate class of reagents (DTC) and the 90 : 10 mixture of collectors added at pH 4.

Figure 3 The difference in heat flux measured when equimolar amounts of potassium *n*-butyl xanthate (PNBX), dithiocarbamate class of reagents (DTC) and 90 : 10 mixture of collectors are added to pyrite at pH 4.

grade pyrite ore using thiol collectors at pH 4. The collectors tested were potassium *n*-butyl xanthate (PNBX) and an alkyl dithiocarbamate collector. Performance was analysed using grade-recovery data as well as water and mass recoveries and the rate of sulfur recovery. The froth surface was analysed using digital image analysis. In all experiments the total molar concentration of collector was constant.

Figure 1 shows the batch flotation results as represented by sulfur grade at 80% recovery, the sulfur recovery at 25% grade and the water recovery, all as a function of mole ratio of components. It is clear that the grades and recoveries are greater than would be expected from a merely linearly additive effect and are synergistically enhanced. Obviously pure collectors may not show linearity with respect to dosages but in the present case the dosages were in the range where these differences were minimal. The change in water recovery, however, was linearly proportional to the molar contribution of the components and clearly the synergistic effect was only influencing the behaviour of the solid particles. Digital image analysis of the froth showed that, when the mixture of collectors was used, the froth was more mobile and the froth surface bubble size was larger. This may be due to the frother-collector interactions, decreasing froth stability, increasing drainage of entrained material and increasing the grades obtained.

In order to elucidate the mechanisms of synergism, the extent of bubble loading and the heats of adsorption were measured for the respective collectors and collector mixtures using pure pyrite at pH 4,

(Figure 1). Figure 2 shows that, for bubbles of average diameter of 1.2 mm, increased bubble loading resulted from the use of a mixture of collectors and Figure 3 shows that when a mixture of collectors was used there was a stronger adsorption than in the case of the pure xanthate, where multilayer adsorption of dixanthogen is indicated, and in the case of dithiocarbamate where pseudo-monolayer adsorption is indicated. In this example, the synergistic effect observed is attributed to increased mineral hydrophobicity, which is thought to be due to the weakly adsorbing dixanthogen adsorbing in multilayers around the strongly adsorbing dithiocarbamate, which acts as a sort of anchor on the surface of the mineral particle. The ultimate result is an increase in bubble loading, an improvement in froth characteristics and a greater grade and recovery.

Bubble-Particle Capture

Introduction

Bubble-particle capture is the heart of froth flotation. For efficient capture to occur between a bubble and a hydrophobic particle, they must *first* undergo a sufficiently close encounter, a process that is controlled by the hydrodynamics governing their approach in the aqueous environment in which they are normally immersed. Should they approach quite closely, within the range of attractive surface forces, the intervening liquid film between the bubble and particle will drain, leading to a critical thickness at which rupture occurs. This is then followed by movement of the three-phase-line contact line (the boundary between the solid particle surface, receding liquid phase and advancing gas phase) until a stable wetting perimeter is established. This sequence of drainage, rupture and contact line movement constitutes the *second* process of attachment. A stable particle-bubble union is thus formed. The particle may only be dislodged from this state if it is supplied with sufficient kinetic energy to equal or exceed the detachment energy, i.e. a *third* process of detachment can occur.

The capture (or collection) efficiency E of a bubble and a particle may be defined as:

$$E = E_C \times E_A \times E_S \quad [1]$$

where E_C is the collision efficiency, E_A is the attachment efficiency and E_S is the stability efficiency of the bubble-particle aggregate. This dissection of capture efficiency into three parts was originally proposed by Derjaguin and Dukhin (1960–61) and focuses attention on the three zones of bubble-particle capture where, in order, hydrodynamic interactions, surface forces and forces controlling bubble-particle aggregate stability are dominant.

This article describes each of the substeps in the bubble-particle capture process. The individual processes and efficiencies are focused upon, since they provide the key to understanding the substeps. Our knowledge of the various efficiencies has been enhanced by six important publications, referred to in **Table 1**, each of which signalled major advances in our understanding and catalysed further research in this interdisciplinary field of colloid and flotation science.

Processes and Substeps

Process 1: Collision Efficiency

For a batchwise flotation process, the flotation recovery (the mass of particles recovered in a given time t) R is given by:

$$R = 1 - \exp - t \left(\frac{3GhE_C E_A E_S}{2d_b V} \right) = 1 - \exp(-tk) \quad [2]$$

where G is the volumetric gas flow rate of a swarm of bubbles of diameter d_b passing through a particle suspension of volume V and depth h , and:

$$k = \frac{3GE_C E_A E_S h}{2d_b V} \quad [3]$$

The flotation rate constant k is directly analogous to that obtained in chemical reaction kinetics. Its value will be partly determined by the substep(s) in bubble-particle collision, attachment and detachment processes, as well as by physical variables such as G . (For a constant G and constant bubble size distribution, d_b will be an appropriate average.)

Equation [2] has been shown to apply, for example, to a system of monodisperse polystyrene latex particles floating under batchwise conditions. A plot of $\ln(1 - R)$ versus t yields the rate constant k . For systems that are polydisperse in particle size and/or in which particles of different hydrophobicities are present, the recovery then becomes the sum of a series of exponential terms and the plot of

Table 1 Key papers in understanding fundamental flotation substeps (details of references are given in Further Reading)

Date	Area of research
1948	A fundamental paper by Sutherland on the kinetics of the flotation process appeared in Australia. This paper invoked induction time, described particle size effects in flotation, and catalysed other similar approaches. While it was preceded by other efforts, this paper was the first comprehensive effort to describe recovery, size and time data in a fundamental manner.
1960–61	In Moscow, Derjaguin and Dukhin produced a key paper on the theory of flotation of small and medium-sized particles. Hydrodynamics, surface forces and diffusiophoresis were all used in this theory. This seminal work resulted in an acceleration of fundamental flotation research worldwide.
1972	Blake and Kitchener, working together in London, published some very careful measurements of the thickness of aqueous films on hydrophobic quartz surfaces. Film thicknesses, measured as a function of salt concentration, were shown to depend on the electrical double layer force. Film instability occurred on hydrophobic surfaces at film thicknesses less than about 60 nm. This value, which was smaller than the range of the electrical double layer force, represented the combined effects of hydrophobic force, surface heterogeneities and external disturbances. Blake and Kitchener's film thickness studies hinted at the length dependence of hydrophobic forces, information which was subsequently obtained by surface force experiments after 1982.
1976	Scheludko and colleagues in Bulgaria considered how particles might become attached to a liquid surface and developed the capillary theory of flotation.
1977	Anfruns and Kitchener published the first measurements of the absolute rate of capture of small particles in flotation. This was the first critical test of collision theory under conditions where the bubble and particle surface chemistry was characterized and controlled.
1983	Schulze published a key textbook on the physicochemical substeps that are important in flotation, drawing on a wide range of hydrodynamic, surface chemical and engineering information. Originally published in German, once translated into English the book captured an international audience.
c. 1980–present	There has been a strong interest in developing reliable collision models (Dai <i>et al.</i> , 1998). The surface force apparatus and, recently, the atomic force microscope colloid probe technique, have provided very useful insight into electrical double layer, van der Waals and hydrophobic forces (Israelachvili, 1985; Fielden <i>et al.</i> , 1996). Thin film drainage has been investigated between a rigid and a deformable interface (Miklavcic <i>et al.</i> , 1995). Attachment efficiencies have been measured (Hewitt <i>et al.</i> , 1995). Reliable methods for measuring contact angles on particles have been developed (Diggins <i>et al.</i> , 1990). Major theoretical and experimental advances in describing dynamic contact angles on well-defined surfaces have been made (Blake, 1993).

$\ln(1 - R)$ versus t will show curvature, reflecting the different contributions to the recovery from the various particles present in the mixture.

In the metallurgical literature, R versus t data are frequently analysed by assuming that the pulp consists of 'fast' and 'slow' floating components, allowing the respective rate constants (k_f and k_s) and fractions (f_f and f_s) to be determined. Although this is a gross simplification of the real multicomponent situation, much valuable information may be gleaned from such an analysis. In fact the latter is frequently used to examine the flotation behaviour of particles of a specific size range in flotation circuits, where the behaviour of an individual flotation cell or bank of cells may be approximated to a batchwise process.

Derjaguin and Dukhin were the first to distinguish three zones of approach of a bubble and a particle

on the basis of the different kinds of force in each zone (Figure 1). This model is a very useful one and helps to identify the various contributions to capture efficiency. However, it should not be taken to mean that there are well-defined boundaries between each zone; rather they grade into one another, the importance of the various contributing effects in each zone being more accurately identified as further information becomes available.

Zone 1 is a region far from the bubble surface where hydrodynamic forces are dominant, controlling E_C in eqn [1]. Hydrodynamic drag forces act to sweep the particle around the bubble, viscous forces tend to retard this relative motion between the two, while particle inertial and gravitational forces move the particle towards the bubble.

Figure 1 Hydrodynamic (1), diffusiophoretic (2) and surface force (3) zones of interaction between a bubble and a particle. (Reproduced with permission from Derjaguin BV and Dukhin SS (1960–61). *Theory of flotation of small and medium-size particles. Transactions of the Institute of Mining and Metallurgy* 70: 221–246, Figure 1).

Broadly speaking, all models of collision efficiency predict that E_C decreases with particle size at constant bubble size down to a particle diameter of about $0.5 \mu\text{m}$. Then, Brownian diffusion probably takes over as the predominant capture mechanism (although this has not been proven), the collision efficiency increasing with decreasing size as the tiny particles (virtually 'solute molecules') move towards the bubble surface. In 1948 Sutherland made the first significant contribution to the treatment of collision efficiency. His hydrodynamic treatment of the process of particle and bubble approach in zone 1 was carried out without any consideration of particle inertia, bubble deformation or film thinning, deficiencies that were in part recognized by Sutherland and Wark in 1955.

The Sutherland theory, based on potential theory or streamline flow, shows that the concentration, C , of mineral floated at a time t is related to its initial concentration, C_0 , by the recovery, R as:

$$R = \frac{C_0 - C}{C_0} = \left\{ 1 - \exp - t \left[\frac{3\pi\phi R_b R_p V_t N_B}{\cosh^2(3V_t \lambda / 2R_b)} \right] \right\} \quad [4]$$

where R_b and R_p are the bubble and particle radii, V_t is the bubble-particle relative velocity, λ is the

induction time, N_B is the number of bubbles per unit volume, and ϕ is the fraction of particles retained in the froth following bubble-particle attachment. The reader should note the relationship between eqns [2], [3] and [4], which are the basis for a first-order model, largely based on pulp microprocesses. Despite the deficiencies of the Sutherland model, his 'first approximation theory' yields results that are in fair agreement with experimental determinations of particle trajectories, touching angles and collision efficiencies, obtained from model experiments performed in a vertical flow tube with individual particles and a single bubble. For more detailed treatments of the hydrodynamic aspects of bubble-particle collision the reader is referred to the extensive literature available.

The inability of collision theories to describe adequately the collection process between bubbles and smooth and angular particles was vividly demonstrated by Anfruns and Kitchener in 1977. Their experiments, the first measurements of absolute rate of capture, gave results in only fair agreement with collision theory, assuming every collision resulted in capture of their very hydrophobic particles.

Process 2: Attachment Efficiency

Derjaguin and Dukhin identified zone 2 in Figure 1 as that region where diffusion effects are important. A strong electric field exists in this zone, since the liquid flow around the moving bubble gives rise to a tangential stream at its surface that destroys the equilibrium distribution of adsorbed ions there. Where surfactant is present it is continually swept from the upper to the lower surface of the bubble. Transport of ionic surfactant to the moving bubble surface therefore takes place, leading to the establishment of a concentration gradient. A strong electric field of order 3000 V cm^{-1} is established when the cation and anion diffusion coefficients differ, as they generally do. Hence charged particles entering zone 2 will experience an electrophoretic force in precisely the same way as in an electrophoresis cell and will be either attracted towards, or repelled from, the bubble surface. The term 'diffusiophoresis' was coined for this phenomenon, i.e. the 'diffusiophoretic force' therefore acts on the particle as an additional force.

To date, however, evidence confirming the presence or absence of diffusiophoresis in flotation is equivocal and sparse. Apart from noting its possible contribution to capture efficiency, it is not pursued further here.

In zone 3, surface forces predominate once the thin film between the bubble and the particle is reduced

much below a few hundred nanometres. These forces can accelerate, retard or even prevent the thinning of the liquid film between the particle and the bubble. From a thermodynamic point of view, the free energy of a liquid film differs from the bulk phase from which it is formed. This excess free energy was originally called the 'wedging apart' or 'disjoining' pressure by Derjaguin and represents the difference between the pressure within the film, p^f , and that in the bulk liquid adjacent to the solid surface, p^l . Note that for a bubble pushed against a flat solid surface, immersed in water, p^b , the pressure within the bubble, is equal to p^f . Derjaguin and his school, as well as Scheludko, performed experimental measurements of disjoining pressures, providing both the first real verification of the DLVO theory of surface forces (named after Derjaguin, Landau, Verwey and Overbeek), as well as the first accurate experimental estimates of the Hamaker constant. The disjoining pressure (π) depends on the film thickness, h , and:

$$\pi(h) = p^f - p^l \quad [5]$$

For mechanical equilibrium in a stable film $\pi(h) > 0$ and $d\pi/dh < 0$.

If the liquid film is stable at all thicknesses the liquid is said to wet the solid completely and the solid is said to be hydrophilic. This occurs, for example, when an air bubble approaches a clean silica surface immersed in water – in this instance the Hamaker constant is negative and the corresponding van der Waals force is repulsive for the silica–water–air triple layer. For an unstable film the thin film must drain, then rupture, and the resulting three-phase line of contact (tpic, vapour–water–solid) must expand to form a wetting perimeter before the particle can adhere to the bubble. Each of these events will have a characteristic time associated with it, the sum of which must be less than the contact time between the bubble and the particle if bubble–particle capture is to occur. The contact time is generally of the order of 10^{-2} s or less. The induction time, λ (see eqn [4]) is normally taken as the time required for bubble–particle adhesion to occur, once the two are brought into contact, i.e. it is the sum of the thin film drainage and tpic spreading times ($t_{\text{film}} + t_{\text{tpic}}$) and is synonymous with the attachment time. Rupture is a very fast process and is not a significant contributor to λ .

When a bubble is pressed against a solid surface, through water, the intervening film is generally not plane parallel. Rather the edge of the film thins quickly and a small, thicker dimple is trapped in the centre, because the bubble is deformable. This is essentially a kinetic phenomenon, caused by the outflow being greatest at the very edge of the film in the initial stages

of drainage. The existence of this dimple has been detected experimentally. Hydrodynamic theories attempting to describe the profile and evolution of the dimple have been proposed but with very limited success in describing experimental data. Surface deformation of bubble surfaces can also occur under the influence of electrostatic interactions (and possibly other surface forces as well) aside from any kinetic effects.

An unstable film arises when there is a net attractive force between the particle and the bubble. This normally occurs when there is an attractive hydrophobic force involved, since the van der Waals and electrostatic forces are repulsive, except in rare circumstances. The measurement of this hydrophobic force, its length dependence and theoretical origins are subjects of intense research effort. In recent times it has become possible to measure the hydrophobic force, in a configuration relevant to the flotation process, by attaching a small particle to the cantilever in an atomic force microscope (Figure 2). The particle is then pressed against a captive bubble and the force–separation distance profile determined. In this fashion, the various surface forces may be explored.

Experimental evidence relating to film drainage in systems where soluble surfactants are present is rather equivocal. Adsorption and desorption processes coupled with possible molecular reorientation make any theoretical interpretation difficult. Unfortunately these are the very systems that are of primary interest to mineral processing. Furthermore additional complications ensue when one considers a particle approaching a bubble in flotation. The nature of the bubble surface (i.e. whether it is mobile or immobile) will influence the thinning of the thin film between bubble and particle. This makes any solution of the Navier–Stokes equation for film drainage difficult, particularly in the case of the

Figure 2 Experimental arrangement for the measurement of forces between a particle and a bubble using the atomic force microscope colloidal probe technique [from Fielden, Hayes and Ralston (1996), *Langmuir*, 12, 3721–3727, with permission].

angular particles that are normally present in flotation. It is worth recalling at this point the observations that smooth spheres float more slowly than angular particles under otherwise identical conditions, presumably because the asperities on the angular particles lead to increased film drainage rates and/or rupture.

The kinetics of movement of the tplc are of central importance in many processes, apart from flotation. During the movement of the tplc a dynamic contact angle is established. Irrespective of whether the 'surface chemical', 'hydrodynamic' or mixed 'surface chemical/hydrodynamic' approaches are used, there is as yet no general theory that adequately describes tplc kinetics on all surfaces. One cannot generally calculate *ab initio* what the spreading velocity of the tplc will be when an air bubble spreads over a mineral surface immersed in water in the presence of a surfactant. Part of the problem at least is due to the fact that poorly characterized experimental systems have been used where any generalization has been obscured by the same time-dependent adsorption/desorption/molecular reorientation processes that complicate thin film drainage rate studies. Physical and chemical surface heterogeneities on the particle surface also strongly influence the tplc kinetics.

At present only the crudest estimates of t_{film} and t_{tpic} can be made. Hence various experimental methods for determining λ are frequently resorted to. A potentially valuable approach to the calculation of induction times, based on bubble deformation and restoration, has been developed.

These experimental methods for determining induction times are generally based on either pressing a bubble against a smooth mineral surface or against a bed of particles. The disadvantages of all current methods for determining λ include: (1) insufficient understanding of the process of bubble deformation and energy dissipation during bubble-particle collision; (2) insufficient information concerning the behaviour of the attractive hydrophobic forces during the bubble-particle interaction (e.g. how the thin film of liquid evolves during the time a particle slides or rolls around a bubble; it may well be incorrect to assume that bubble-particle interaction ceases when the particle passes the bubble equator); (3) the absence of data on t_{film} , e.g. influence of surfactant type and concentration on thin-film drainage mechanisms and rate; and (4) the absence of data on t_{tpic} as a function of hydrophobicity, physical and chemical surface heterogeneities and surfactant type.

The most appropriate method for determining induction times is probably through direct observation of bubble-particle interactions in a flotation cell under well-defined conditions. The necessary theory can

then be developed. For the present the Sutherland and similar approaches (eqn [4]) serve as useful approximations in determining λ from experimental flotation data of the type normally generated.

Kinetic effects certainly have a strong influence on bubble-particle collision and attachment efficiencies. The latter provides the key to selective separations in flotation. Once attachment has occurred, the interplay between particle size and contact angle in the environment of the flotation cell becomes of paramount importance and is the next subject of our discussion.

Process 3: Stability Efficiency and Detachment

Flotation limits for coarse particles The essential problem in understanding bubble-particle aggregate stability is to determine whether or not the adhesive force, acting on the tplc, is large enough to prevent the destruction of the aggregate under the dynamic conditions that exist in flotation. It is important to understand the physics of the problem before moving on to a mathematical description. Let us consider a smooth spherical particle located at the fluid interface. Once the equilibrium wetting perimeter has been established following spreading of the tplc, the static buoyancy of this volume of the particle will act against the gravitational force (Figure 3). The hydrostatic pressure of the liquid column of height Z_0 acts against the capillary pressure. The 'other detaching forces' require further discussion. Since they arise from the particle motion relative to the bubble, velocity-dependent drag forces will oppose the detachment of the particle from the bubble. An analysis of these forces is extremely complex and has not been reported to date. Therefore any force balance will necessarily be quasistatic and approximate.

The net adhesive force, F_{ad} , is equal to the sum of the attachment forces, F_{a} , minus the detachment forces, F_{d} , i.e.:

$$F_{\text{ad}} = F_{\text{a}} - F_{\text{d}} \quad [6]$$

Figure 3 Location of a smooth spherical particle at a fluid interface. (From Schulze (1983) *Physicochemical Elementary Processes in Flotation*. Amsterdam: Elsevier.)

The particle will not remain attached to the bubble if F_{ad} is negative but will be present in the liquid phase.

The mathematical description of the various forces that dictate the equilibrium position of particles at liquid-vapour or liquid-liquid interfaces has followed an evolutionary trail. Analogous processes of interest, for example, include pigment 'flushing', where a solid particle is induced to transfer from one liquid phase to another by appropriate surface modification with surfactants, and the stabilization of emulsion droplets by solid particles.

The actual problem of the balance of forces operating on a particle at a liquid-air interface has been considered by Sutherland and Wark, who considered the case of a gas bubble attached to a plane solid surface of infinite extent and used this as a model for bubble-particle adhesion in flotation. Since this work there have been other very notable contributions. It was Princen who proposed the first extensive and generalized treatment of the forces acting on a particle at fluid interfaces. This theory was developed further by Schulze in 1977 and expanded in 1983.

Consider the case of a spherical particle at a liquid-air interface. We assume that the system is in a quasistatic state and that the contact angle corresponds to that for a static system. The dynamic contact angle can depart significantly from the static value, depending in part on the velocity of the tpic. If the particle oscillates around its equilibrium position, the tpic would be expected to move to some extent. Hence a full analysis would need to account for the velocity-dependent drag forces mentioned above and link these to contact angle dynamics. Since this is an intractable problem at present, a simpler approach is necessary.

Let us suppose that a spherical particle of radius R_p is attached to a bubble of radius R_b where R_b is much greater than R_p , as shown in Figure 3. By understanding the forces that operate on the particle, it is possible to calculate the energy of detachment. The forces acting upon the particle are as follows:

- Capillary force, F_c , acting in the vertical direction along the tpic:

$$F_c = 2\pi r_0 \gamma \sin \phi_0 = -2\pi R_p \gamma \sin \omega [\sin(\omega + \theta)] \quad [7]$$

where γ is the liquid-vapour surface tension.

- Static buoyancy of the fractional volume of the immersed particle, F_b :

$$F_b = \frac{\pi}{3} R_p^3 \rho_l g [(1 - \cos \omega)^2 (2 + \cos \omega)] \quad [8]$$

- Hydrostatic pressure, F_h , of the liquid column of height Z_0 on the contact area:

$$F_h = -\pi r_0^2 \rho_l g Z_0 = -\pi R_p^2 (\sin^2 \omega) \rho_l g Z_0 \quad [9]$$

- Capillary pressure, F_p , in the gas bubble which acts on the contact area πr_0^2 :

$$F_p = P_g \pi r_0^2$$

which for a spherical bubble is given approximately as:

$$F_p \approx \pi R_p^2 \sin^2 \omega \left(\frac{2\gamma}{R_b} - 2R_b \rho_l g \right) \quad [10]$$

- Gravitational force, F_g :

$$F_g = \frac{4}{3} \pi R_p^3 \rho_p g \quad [11]$$

where ρ_p is the particle density.

- Extra detaching forces, F_d , which are denoted approximately and generally as the particle mass multiplied by a generalized acceleration b_m in the flotation cell:

$$F_d \approx \frac{4}{3} \pi R_p^3 \rho_p b_m \quad [12]$$

It is worth remarking that it is bubble-particle aggregates that are actually accelerated in the flotation device, thus ρ_p is in fact an approximation ($\Delta\rho = \rho_p - \rho_l$).

At equilibrium, the sum of these forces, $\sum F$, must equal zero.

The energy of detachment, E_{det} , corresponds to the work done in forcing a particle to move from its equilibrium position, $h_{eq}(\omega)$ at the liquid-vapour interface to some critical point, $h_{crit}(\omega)$, where detachment occurs and the particle moves into the liquid phase. The sum of the various forces, $\sum F$, is related to E_{det} by:

$$E_{det} = \int_{h_{eq}(\omega)}^{h_{crit}(\omega)} \sum F dh(\omega) \quad [13]$$

Equation [13] may be solved by introducing the various forces and carrying out a numerical integration. The detachment process takes place when the kinetic energy of the particle equals E_{det} . The kinetic energy of the particle is given by $\frac{2}{3} \pi R_p^3 \rho_p V_t^2$, where V_t is the relative (turbulent) velocity of the particle, acquired due to stresses on the bubble-particle

aggregate in the turbulent field of the flotation cell, as the aggregate collides with other bubbles or aggregates or due to other modes of excitation. V_t is determined experimentally as the velocity of gas bubbles in the flotation cell and ρ_p is the density of the particle.

The maximum floatable particle diameter based on the kinetic theory, $D_{\max,K}$, is given as:

$$D_{\max,K} = 2 \left[\frac{3}{2\pi\rho_p V_t^2} \int_{h_{eq}(\omega)}^{h_{crit}(\omega)} \left\{ \frac{2}{3} \pi R_p^3 \rho_1 g \right. \right. \\ \times \left[1 - \frac{2\rho_p}{\rho_1} - \cos^3 \omega + \frac{3h}{2R_p} \sin^2 \omega \right. \\ \left. \left. - \frac{3}{a^2 R_p^2} \sin \omega \sin(\omega + \theta) \right] \right. \\ \left. \left. - \pi(R_p \sin \omega)^2 \left(\frac{2\gamma}{R_b} - 2R_b \rho_1 g \right) \right\} dh \right]^{1/3} \quad [14]$$

Equation [14] may be solved by numerical integration or by plotting each of the kinetic and detachment energies as a function of R_p at constant γ and ρ_p and specified V_t . ρ_1 refers to the density of the fluid and γ is the surface tension at the liquid-vapour interface. This equation has been shown to describe adequately both the detachment of a sphere from a liquid-vapour interface and the behaviour of hydrophobic angular quartz particles between approximately 30 and 120 μm in diameter under flotation conditions.

Flotation limits for fine particles The only theoretical study to date dealing with the limit of floatability of fine particles was published by Scheludko and co-workers in 1976. The limit is the critical work of expansion required to initiate a primary hole or three-phase contact line during bubble-particle approach – a requirement that is met by the kinetic energy of the particles. The matching of these two quantities enables a minimum particle diameter, $D_{\min,K}$, for flotation to be obtained:

$$D_{\min,K} = 2 \left[\frac{3\kappa^2}{V_t^2 \Delta\rho \gamma \{1 - \cos \theta\}} \right]^{1/3} \quad [15]$$

where κ is the line tension, opposing expansion of the tpic. Molecules that are present in a line have a free energy that is different from those at a surface – in fact there is an excess linear free energy and a linear tension in an analogous fashion to that of excess surface free energy and surface tension.

In fact,

$$\kappa = \left(\frac{\partial F}{\partial L} \right)_{T,V,W} \quad [16]$$

where F is the Helmholtz free energy, L is the contact line, T is the temperature, V is the volume and W is the thermodynamic work. The Young-Dupré equation becomes:

$$\gamma_{S/V} - \gamma_{S/L} = \gamma_{L/V} \cos \theta \pm \frac{\kappa}{r} \quad [17]$$

The line tension is important for small contact radii and can oppose or reinforce $\gamma_{L/V} \cos \theta$. It counteracts the formation of the tpic in Scheludko's theory which neglects thin film drainage and other hydrodynamic effects. Experimental data for hydrophobic, angular quartz particles between about 10 and 35 μm in average diameter follow a general trend that is predicted by eqn [15], although quantitative agreement is poor. If a pseudo-line tension, embracing surface heterogeneities, replaces κ in eqn [15], then this in turn enables D_{\min} in eqn [15] to be re-expressed in terms of a critical bubble radius below which attachment does not occur. Reconciliation between theory and experiment is then achieved although the concept of pseudo-line tension needs to be placed on a firmer experimental foundation.

The Future

In terms of our fundamental understanding, there is no entirely adequate collision model that can correctly account for particle size and inertial effects in the presence and absence of soluble surfactants. Thin film drainage is poorly understood when one of the interfaces is both physically and chemically heterogeneous, and the other is deformable. The nature of the hydrophobic interaction between a particle and a bubble requires both experimental and theoretical verification. There is no reliable model at present to describe the movement of a three-phase contact line over a physically and chemically heterogeneous surface. Thus major research challenges exist that, if they are to be successfully overcome, must embrace systems where surfactants are both present and absent.

From a separation technology point of view, froth flotation will continue to be one of the principal means by which ores are successfully beneficiated for many years to come. Increasingly the technique is also being used in the deinking of paper, soil remediation, plastics recycling and heavy metal ion decontamination, to name but a few examples. Both research and practice are expected to accelerate strongly over the next decades as new techniques and theoretical approaches are used.

Introduction

History

The first pneumatic flotation cell, which used air sparging through a porous bottom and horizontal slurry flow, was patented in 1914 by Callow. The first countercurrent column flotation device was designed and tested by Town and Flynn in 1919. Cross-current

pneumatic flotation machines were widely used in industry in the 1920s and 1930s, but were later replaced by the impeller-type flotation devices in mineral-processing plants. Dissolved-air flotation became the main type of flotation for water treatment applications. These substitutions were the result of the absence of effective and reliable air spargers for fine bubble generation and the lack of automatic control systems on the early columns. During this period, both the poor flotation selectivity and entrainment of slimes characteristic of impeller-type cells were offset by the use of complex flow sheets using large numbers of cleaner stages and recycle lines. Column flotation devices were reintroduced

for mineral processing in Canada by Boutin and Wheeler in 1967, at which time washwater was added to the froth to eliminate entrainment of hydrophilic materials to the float product. By the late 1980s column flotation had become a proven industrial technology in the mineral industry. These separators are routinely used on their own or in conjunction with other types of devices within separation circuits. This technology is currently being applied to liquid-liquid separations (oil-water, organic solvent-liquid), solid-liquid, or solid-solid separations in many industries.

Comparative Strengths and Weaknesses

Column cells are flotation devices that also act as three-phase settlers where particles move downwards in a hindered settling environment. Within the vessel there is a distribution of particle residence times dependent on settling velocity that may impact on the flotation of large particles. Impeller devices do not suffer from this effect to the same degree but do require higher energy input to suspend larger particles.

The low turbulence in columns means particles usually have low momentum, which in turn may reduce the probability of collection by passing bubbles. As a result, fine particle recovery may be hindered when compared to the capabilities of impeller-type designs.

The mechanism of particle-bubble collision in columns is different from intensive mixing devices such as impeller cells. Under the low intensity mixing caused only by a rising bubble swarm, particle drift from the liquid streamlines is caused mainly by gravity and inertial forces and also by interception, while in mechanical cells, according to many researchers, bubble-particle collision occurs at their relative movement within a turbulent vortex or at adjacent vortices. Also, as velocities of both bubble and particle during the attachment are slower under the quiescent conditions in a column, the contact time is generally higher. Therefore, probabilities of both collision and adhesion (components of attachment probability) are different to those in mechanical flotation processes.

The lower velocity gradient and less intensive shear forces in the vicinity of rising bubbles under low turbulent conditions in a column lead to reduced detachment probability. The latter is most important for improvement of recovery for coarse, heavy or weakly hydrophobic particles.

A column can support a deep froth bed and may use washwater to maintain a downward flow of water in all parts of the vessel. This essentially eliminates the entrainment of hydrophilic particles in the

float product when the vessel is used for solid-solid separation. This property, along with the absence of stray flows of feed material to the float product by turbulence, means that column devices are normally superior to impeller-type machines for the selective separation of fine particles.

In immiscible liquid separation duties, columns do not emulsify the material like impeller devices.

The bubbles used in a column are usually generated within the size range that maximizes interfacial surface flux and collection intensity through the vessel. Dissolved air systems nucleate micrometer-sized bubbles on particles which require very low downward liquid velocities in large volume vessels to separate the bubble and water. Also, dissolved air systems cannot provide air hold-up higher than approximately 4–6%, due to limited gas solubility and lower flooding limits caused by the microbubbles. In mechanical cells, bubbles are usually generated by shear action of the impeller; thus, bubble size is dependent on both air flow rate and impeller rotation speed. As such, bubble size cannot be controlled independently of cell turbulence.

The height-to-diameter ratio of a column is significantly higher than the impeller-type machines. As a result, control and consistency of flow are more critical. The column requires much less floor space to operate.

Control Systems

Control systems are designed to maintain separation in a changing environment by maintaining operating variables at their optimum values for process performance. The configuration used depends on the variability of the vessel feed, the ability of the operating and instrumentation staff, the availability of detectors and other parts, capital costs and the goals of the project. The most basic system only controls the interface level, between the aqueous suspension and froth phases, while complex systems can integrate expert systems or other forms of artificial intelligence into a full-grade/recovery adjustment strategy.

All columns perform best when flows are constant, therefore operation should be as close to steady-state conditions as possible. Good control systems limit damage due to variations by maintaining constant flows in earlier stages, establishing a recycle within the column system, or compensating by changing conditions within the vessel.

Level

The goal of a level control system is to maintain a constant aqueous suspension depth despite changes

Figure 1 Example of level control loop. LT, level transmitter; LIC, level indicator and control; LY, level D/A signal conversion; LCV, level control device; MAG, magnetic flow detector; FT, flow transmitter; FI, flow indicator; PID, proportional-integral-derivative; PLC, programmable logic controller.

in feed flow, floatable material concentration or air rates. An example of this control is found in **Figure 1**. In water-oil separation, a periodic level rise may be organized to dump an accumulated organic pad. The simplest method of controlling level is to adjust the discharge height of the underflow using a 'gooseneck' or alternative form of gravity control. If this is not possible, then the level must be detected and that signal used to control either a variable-speed pump or control valve through a controller device. Detection devices include floats; pressure, capacitance, conductance, and ultrasonic transducers, or combinations of these devices. The set point for the level is determined from the desired froth depth. Generally, the higher the level, the greater is the recovery of the floating component and the lower its content in the overflow

(froth product). In more complicated systems, the level control may be used with froth or oil pad depth data to control overflow grade, with flow-monitoring devices for predictive control based on incoming feed, or multiple monitors to compensate for variations in air rate or feed composition.

Air

The purpose of the air loop is to control a volumetric flow of air through the column or to maintain a three-phase density within the vessel. In basic control systems air rate is controlled manually based on a monitored air flow rate. In slightly more advanced systems, the flow is controlled through an automatic valve to compensate for pressure changes (**Figure 2**).

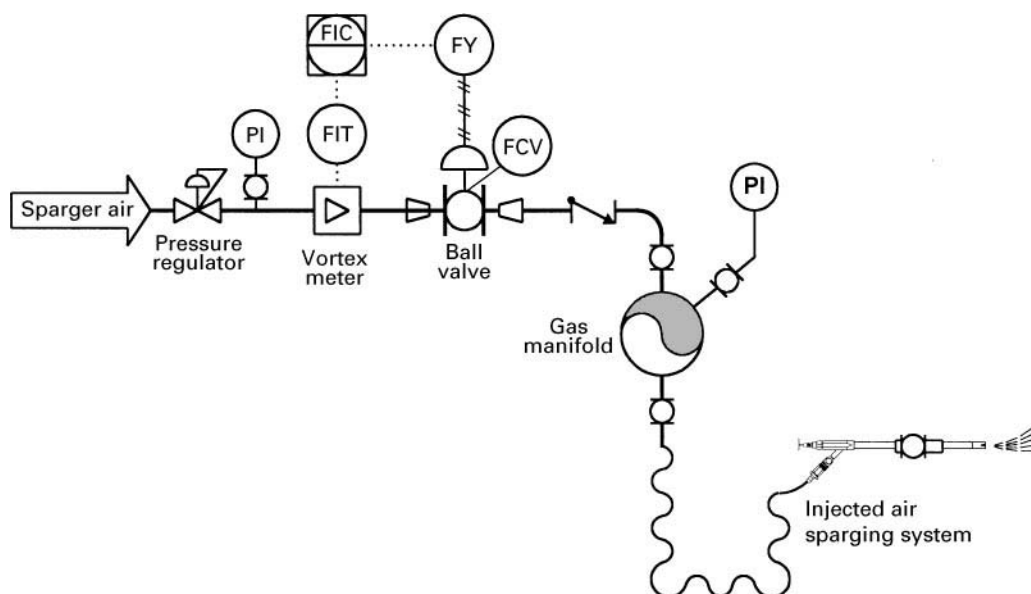

Figure 2 Example of air control loop. PI, pressure indicator; FIT, flow indicator and transmitter; FIC, flow indicator and controller; FY, flow D/A signal conversion; FCV, flow control device.

Air rate may be linked to predictive- or recovery-based systems.

Bias

Bias is defined as a downward flow of liquid through the froth zone. Positive or downward bias is usually used when two suspended substances must be separated from each other. If multiple separation stages are in operation, it is usually used on the last stage. The downward flow of water through the froth is controlled by varying the water rate added to the froth zone. This flow may be monitored by temperature, conductance or by flow differences (water added to froth minus overflow water, or amount of liquid in underflow minus its amount in feed). The actual bias needed depends on the distribution of the water through the froth and the hydrophilic particle sizes.

Bias may be estimated using the difference in slurry flows (**Figure 3**) or, more accurately, by first calculating the liquid volumetric flows using flow and density meters.

Advanced Controls

It is possible – although not common – to control a column to separate according to a grade-recovery response curve. As grade increases or decreases in the feed, level, air rate and bias may be adjusted to achieve the most economical performance. This type of control requires a good predictive model based on theoretical knowledge, past experience and test work that uses information from upstream processes to

adjust column parameters in anticipation of changes (feed-forward control). Predictive systems provide feed-forward control and can incorporate either knowledge base or models (statistical or deterministic) into the control loop. Excessive complexity of models or control strategy does not improve the results as the uncertainty in parameters grows. Such a system also requires extensive online detection equipment such as density, flow and pressure meters. When these controls are implemented they are either model-based systems or some form of artificial intelligence (knowledge base, neural network systems based on fuzzy logic principles).

Operating Parameters

Process-operating variables are those inputs to the separator that may change with time and can be used to control the production quantity and quality. These include column control variables such as gas rate, washwater rate and froth or oil pad levels. There are also variables that may be controlled but are usually not even monitored, like bubble size distribution, and variables that depend on other parts of the operation such as volumetric feed rate, and feed solids characteristics: concentration, liberation and particle size distribution.

Gas (Air)

Gas (air) rate is an effective parameter to control separation since the probability of particle collision

Figure 3 Example of differential feed-underflow bias control loop. LCV, level control device; LY, level D/A signal conversion; LIC, level indicator and control; FT, flow transmitter; MAG, magnetic flow detector.

with bubbles is dependent on the number of bubbles and their size distribution. The maximum particle surface flux removed depends on bubble surface area flux. As surface area flux increases, so does the probability of material-bubble aggregation (collection) within a specific range. This range is bounded by the increased mixing intensity as flooding limits are approached and the increase in bubble size that is usually associated with an increase in gas flow. The total removal capacity, known as carrying capacity, can also be controlled by the gas rate since it is proportional to the specific bubble surface area. The carrying capacity is determined as the maximum amount of material which can be transported into froth in unit time from a unit cross-sectional area of a column. It varies depending on particle size (for solid separation) and density of the floating substance. The carrying capacity can be estimated from the balance

of the available bubble surface area and particle surface flux. The normal range of superficial air velocity is $1.0\text{--}2.5\text{ cm s}^{-1}$. In buoyant material separations, high gas rates may reduce the three-phase density of the aqueous suspension within the column to a density lower than that of the product. This will cause an unstable pad that will sink if not quickly removed from the system.

Volumetric Feed Rate

The volumetric feed rate determines the vessel retention time and strongly influences vessel mixing. An increase in superficial suspension velocity results in lower gas limits as flooding will occur at lower gas rates and increases the size of microbubbles which become entrained by downward flow to the underflow. However, higher slurry velocities also decrease

the negative influence of mixing on grade and recovery (higher Peclet number) and lessen the retention time difference between fine and coarse particles due to the settling. Typically, superficial feed velocity is $0.5\text{--}1.3\text{ cm s}^{-1}$.

Feed Solids

An increase in the percentage of solids contained in the feed increases the residence time of those solids in the case of constant-column throughput of solids. The maximum solids load is determined by the viscosity of the system and may be only 0.25–2% (weight/weight) for paper de-inking applications to almost 70% for calcite/silica separation.

Washwater

Mineral separation columns can provide a positive bias which causes displacement of the feed liquid phase with washwater in the overflow. This substitution virtually eliminates entrained fines from the overflow product. Washwater distribution on to or into froth and its flow rate should be individually tuned for each application depending on feed and concentrate size distributions, froth stability, height and mobility, and on process objectives. Excessive washwater supply causes froth disruptions, loss of recovery and dilution of products. Typically, superficial washwater flow rate does not exceed 0.15 cm s^{-1} , although optimal rates depend on washwater distribution design and froth rheology. Washwater is not normally used in mineral roughing or scavenging operations, oil–water separations, or systems where entrainment is not a factor.

Froth Depth (Solid Separation)

The froth level maintained within the column is highly variable depending on the application. Some vessels may be operated with no froth, such as oil–water separators, or mineral columns operating on very large particles. In other cases, like molybdenite flotation, a froth as deep as 1.5 m may be run to ensure minimal entrainment and high selectivity. In general, a deep froth gives more opportunities for grade/recovery control and compensates for poor washwater distribution. Froth depth in mineral (solid–solid separation) column flotation typically varies from 15 to 300 cm. The gas hold-up in froth gradually increases upwards due to froth sineresis and drainage along plateau canals. The entrained fine particles return back to the lower (collection) section of the column by net downward liquid flow in the froth (in the case of positive bias). Experimental data confirm that, in some cases, upgrading of the product

occurs mainly in the froth zone, and not at the collection stage.

It is important to note that an increase in froth depth decreases the volume of the remainder of the column which may be detrimental to overall performance.

Organic Pad (Liquid Separation)

In an oil separation vessel a hydrocarbon pad may be maintained at the top of the column. A deep pad minimizes water entrainment into the overflow but may increase the stripping of light hydrocarbons. When high air rates are used and the organics pad is not removed, droplets of organic phase may form and drop through the aerated zone of the column. Air rates must be lowered or the organics pad continuously removed as a froth to prevent sinking of the floated organics.

Bubble Size

Some types of spargers allow the change of bubble size distribution at nearly constant overall air rate. Both break-up and coalescence of bubbles occur after formation by the sparging devices which results in an equilibrium size distribution above a certain distance from the spargers. The average and deviation of this distribution depend on the surface tension at the air–water interface and turbulence in the cell. Generally, smaller bubbles provide higher collection intensity and carrying capacity, but loaded microbubbles may sink or be entrained in the downward slurry. Also, maximum gas rate (at column flooding point or transition to a churn-turbulent regime) is reduced with decreasing bubble size, meaning that there is a specific bubble size that gives the maximum upward rising surface area flux. The point of column flooding can be estimated (in the assumption of cross-section flow uniformity and narrow bubble size distribution) from the drift flux model. In many cases a combination of smaller bubbles that provide the separation and coarser transport bubbles that coalesce with the smaller bubbles results in optimal flotation rates.

Column Circuits

Column cells can be used to perform many functions. These include separation within a grinding circuit (unit cell), as an initial (primary or rougher) or scavenging separator whose purpose is maximum recovery of material, or as a final separator (cleaner or recleaner) used to produce a pure product. They can also be used to process bleed streams from other processes. There are many examples of column usage, including base metal and industrial mineral

separation, iron ore purification, coal cleaning, solvent extraction and oil–water separation, paint recovery and newspaper de-inking. In addition, columns can be used to remove hydrophobic substances, or materials dissolvable in hydrophobic liquids, from water or soils. Examples are DDT, polycyclic aromatic hydrocarbons (PAHs) or other dangerous chemicals, oil production from tar sands, or the purification or removal of algae or bacteria from cultures. All of these separations fall into three categories: solid–solid, solid–liquid and liquid–liquid separations.

Solid–Solid Separations

In order to get a good separation, the solids present must be liberated: that is, not physically or chemically attached, be suspended in a liquid medium and the flotation kinetics of the materials must be different. One or more stages of separation may be needed, depending on the kinetics and chemistry of the separation. To achieve sharper separation when difference in flotation rate of components is not high and/or material is not completely liberated, complicated flowsheets including multiple recycle lines and regrinding are used. Regrinding operations for middlings are used to avoid over-grinding of the bulk of material as it would cause reduction in flotation rate and selectivity for fine particles. For finely disseminated ores, entrainment is a substantial factor

reducing sharpness of separation. Entrainment is a process of particle transfer to froth without their attachment on to bubble surfaces. This phenomenon can be explained by movement of small particles in the wake behind the rising bubble or within the static layer of liquid surrounding it. In machines with intensive mixing (impeller cells) the entrainment can also be caused by local upward slurry flows. These flows are not present in columns therefore reducing overall entrainment intensity and improving separation efficiency. A classical flotation flowsheet includes several cleaning stages generally linked by recycle of the cleaner tailings to previous stages. When more than one material is floatable and separation depends only on degrees of hydrophobicity (molybdenite–chalcopyrite), four to six stages may be required. If insufficient recovery is achieved in the primary vessel (rougher flotation), scavenger cells may be used. In general, all stages do have a common separation goal. For example, silica (impurity) is floated away from hematite in a four stage iron ore circuit in **Figure 4**. This circuit, or variations of it, is common when the valuable product is hydrophilic or an under-flow product of the column. The example gives four stages of separation; however, in many cases fewer stages are required.

The circuit for a hydrophobic product is shown in **Figure 5**. The second cleaner stage of this circuit is generally not needed unless the separation is between

Figure 4 Hydrophilic product, solid–solid four-stage separation circuit. Example of iron ore.

Figure 5 Hydrophobic product, solid–solid four-stage separation circuit. Example of copper or plastics float.

hydrophobic materials with similar flotation rates. As an example, this configuration or variations of it can be used in phosphate, copper, zinc and plastics separations, or for soil remediation.

Solid-Liquid Separations

In many circumstances a solid is present in a liquid stream that must be removed. Flotation is often a viable precursor stage, used to increase the percentage of solids, prior to filtration. This type of system can be used to float coal and associated PAHs from run-off water and upgrade the percentage of solids from p.p.m. levels up to 10–25%. **Figure 6** gives an example of such a circuit where PAHs from coking coal are floated from a contaminated site run-off

water without removing the naturally occurring sand and silt.

Flotation can also be considered as an alternative to settling of naturally hydrophobic materials in wastewater treatment. This type of separation may also be used to remove bacteria or algae from water, or many solid substances from reaction vessels.

Liquid-Liquid Separations

Immiscible liquids of any kind can be separated from water by flotation. The bubbles act to increase the kinetics of the naturally floating droplets such as diesel, crude oil, kerosene or the organics used in solvent-liquid extraction processes. Some examples are hydrocarbon separation from water on oil

Figure 6 Example of solid-solid separation: PAH from run-off water. Input of approximately 500 p.p.m. solids; filter feed of approximately 24% solids.

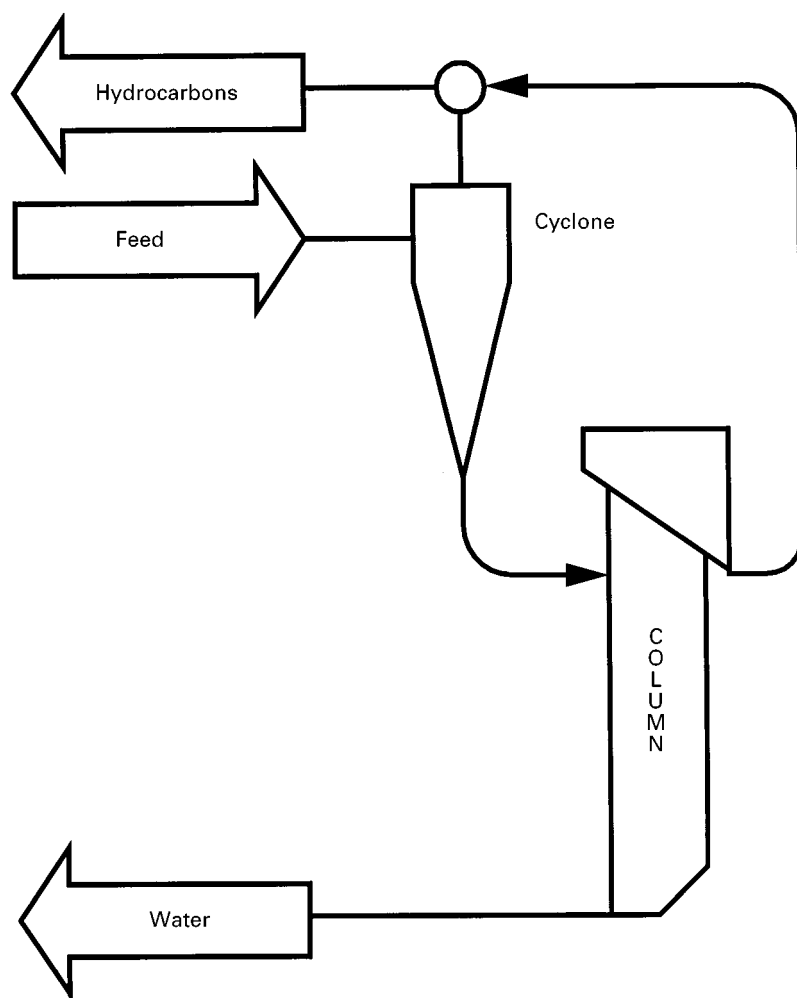

Figure 7 Treatment of oil platform process water; generalized circuit.

production platforms prior to final release of water, site run-off remediation and organics separation in hydrometallurgy. Columns are capable of removing freely floating hydrocarbons but usually not emulsified or dissolved hydrocarbons. In order to remove emulsified forms of hydrocarbons, a pre-aeration unit must be installed.

Oil production application Large amounts of water are involved in the extraction and production of oil. Column cells are used in the water treatment stage of production prior to release of the water back into the environment. In a typical circuit, as shown in **Figure 7**, water from the process is first passed through a cyclone or corrugated plate separator then to a column. The hydrocarbon concentrate from both of these vessels is returned for processing.

Site run-off remediation Sites that contain hydrocarbon contamination such as refineries and distribu-

tion depots often have run-off waters that contain entrained hydrocarbons. These can be treated effectively with flotation technology using a circuit containing a column either working on its own or in conjunction with a settling tank. If emulsified hydrocarbons are present, a pre-aeration unit may be required on the column in order to achieve contamination level under 15 p.p.m.

Organic-aqueous separation in solvent-liquid extraction circuits The solvent liquid extraction circuits employed in most hydrometallurgical processes require the removal of essentially all of an organic solvent from an aqueous medium in more than one stream. Initial separation is usually done in settlers. Columns with or without a pre-aeration unit can be used as secondary separation devices prior to filtering. The advantage of columns over many other devices is their ability to compensate for wide fluctuations in both aqueous and organic flows.

Conclusion

Column flotation has become the standard proven industrial flotation technique rather than an experimental method during the last decade. Nevertheless, its use in mineral-processing plants is mainly restricted at present to cleaning operations. The future of flotation equipment development lies in the combination of the advantages of impeller and column flotation and in the use of pneumatic machines in roughers.

As a greater share of flotation operations are used for unconventional areas such as environmental applications (water treatment, soil remediation, etc.) and ultrafine and colloid particle separation, special machines will be developed combining flotation attachment at intensive aeration and mixing conditions and three-phase separation in a quiescent environment. This leads to the concept of pre-aeration in a reactor (a unit for attachment of recovering phase on to gas bubbles) and de-aeration in a separator (a unit for separation of loaded bubbles from the bulk of three-phase suspension). Additional coarser bubbles can be added in a separator as a carrier to enhance the removal of loaded microbubbles by coalescence.

This concept and other types of new combined flotation machines will provide for more effective

and efficient separation for a wide range of applications.

Cyclones for Oil/Water Separations

Bradford, UK

Copyright © 2000 Academic Press

Synopsis

Though the solid–liquid hydrocyclone has been established for most of the 20th century, satisfactory liquid–liquid separation performance did not arrive until the 1980s. The offshore oil industry had a need for compact, robust and reliable equipment for removing finely divided contaminant oil from water. This need was satisfied by a significantly different

type of hydrocyclone, which of course had no moving parts.

After explaining this need more fully and comparing it with solid–liquid cyclonic separation in mineral processing, the advantages that the hydrocyclone conferred over types of equipment installed earlier to meet the duty are given.

Separation performance assessment criteria are listed prior to discussing performance in terms of feed constitution, operator control and the energy required, i.e. the product of pressure drop and flowrate.

The environment for petroleum production sets some constraints for materials and this includes the problem of particulate erosion. Typical materials

used are mentioned. Relative cost data for types of oil separation plant, both capital and recurrent, is outlined, though sources are sparse. Finally, some pointers to further development are described, as the oil industry looks to equipment installed on the sea bed or even at the bottom of the wellbore.

Introduction to Liquid-Liquid Hydrocyclones

This article covers the application of hydrocyclones to remove or concentrate dispersed oil from water. Two main classes of operation relating to their use with water-continuous liquid exist. Firstly as removers of oil contaminant from water (clean-up units) and secondly as a method of de-watering crude from wet oil fields (concentrator units). It excludes usage in relation to oil spills at sea, though feasibility studies have been technically successful. It also excludes applications where dispersed water (brine) is found in oil, though articles on this application – as yet only on the fringe of commercialization – may be found in the Hydrocyclone Conferences listed in the bibliography. Operation with oil-continuous liquid is difficult since interfacial effects are larger and break-up more likely as the brine droplets are less viscous than the continuous liquid.

Table 1 lists the key stages in arriving at the present near-universal usage of hydrocyclones for removal of oil contaminants from water in the oil industry offshore and more recently onshore. Concentrators, sometimes called ‘dehydration hydrocyclones’, are used in very wet oilfields as the initial stage to reduce the water (brine) content from, say, 95% to 50% or less. Under some conditions the overflow stream inverts to become oil continuous.

The two decades since de-oiling hydrocyclones were first seen to be capable of reaching legal standards of cleanliness offshore, e.g. 40 mg kg⁻¹ maximum free oil on the UK Continental Shelf, are brief when compared with the much longer and wide-

spread employment of solid-liquid hydrocyclones as in mineral processing or china clay production. Some salient comparisons between the two categories and the consequences of the clean-up or concentrator duty are set out in **Table 2**.

Flowfield and Geometry

The dispersion of fine oil droplets and their low differential density necessitate a high radial acceleration field. Since the oil is buoyant it will migrate towards the vortex core. To understand separation performance it is helpful to stress consequences of these two points. The oil is much more sensitive to the flow pattern than solid particles so this leads to the requirement for a low turbulence, reasonably linear vortex core and low peak shear flowfield to avoid droplet break-up leading to lower oil removal efficiencies.

The overflow stream should be a small fraction of the feed, since the oil content in clean-up applications is typically below 1%. An approximate volumetric balance gives the interrelationship between the parameters of a de-contaminating hydrocyclone. If the volumetric feed concentration of oil $C_f \sim 1\%$ and the overflow and underflow concentrations C_o, C_u are assumed to be 50% and 0 respectively, then the underflow rate Q_u will be 98% of the feed rate Q_f . For a wet oil concentrator however assuming $C_f \sim 10\%$ Q_u will be $\sim 80\%$ of Q_f . The overflow (reject) stream flow rate clearly is $Q_o = Q_f - Q_u$.

Colman and Thew at the University of Southampton in the late 1970s found that a cone angle as small as $1-1\frac{1}{2}^\circ$ (total angle) produced the necessary stable vortex, with a small relatively fast moving core moving to the overflow. This reverse axial flow penetrated a long distance downstream, so that in the early work a cylindrical tailpipe was put on the end of the cone. They also found that an enlarged entry section, as illustrated on **Figure 1**, reduced the pressure drop and reduced peak shear; the left-hand side of **Figure 1** shows the approximate proportions of the

Table 1 Advances in the use of oil-water hydrocyclones

1950s and 1960s	Sporadic work on liquid-liquid hydrocyclones, especially in relation to use in the atomic energy industry
1965	Bradley produces his classic text on ‘Hydrocyclones’ clarifying the problems of liquid-liquid separation
1974	Kimber and Thew achieve 90% oil separation at Southampton University, UK
1978–80	The Southampton Group achieve > 99% separation with crude oil (Colman and Thew, 1980 Hydrocyclone conference)
1983–84	First field trials offshore
1985	First large offshore installation (15 m ³ min ⁻¹)
Late 1980s	Installations worldwide
1990s	Virtually only method of oil-water separation. Number of manufacturers grows, prices fall. Higher mechanical packing density in pressure vessels
Early 1990s	Use in concentrator mode begins
Late 1990s	‘Downhole’ trials begin

Table 2 Comparisons between solid-liquid and oil-water hydrocyclones

<i>Factor</i>	<i>Solid-liquid</i>	<i>Oil-water</i>
Differential density	Often water-quartz, 1650 kg m^{-3}	$50\text{--}300 \text{ kg m}^{-3}$
Split ratio (Q_U/Q_F)	Fixed; set by outlet orifice size	Controllable by external valves
Outlets	Usually one or both open to atmosphere	Closed system
Axial pressure gradient near the centre line	Usually very small (air core)	Substantial, overflow at lower pressure than the underflow
Pressure drop	1–5 bar	5–20 bar
Inlet pressure	1–5 barg	10–10 ² barg
Shear	May cause some size reduction due to particle-particle interaction	Likely to cause droplet break-up
Particle size	1 μm –10 mm	Usually droplets $\sim 1 \mu\text{m}$ –100 μm
Concentration (by volume)	Varies greatly; can be slurry at underflow	Typical oil contaminant concentration in feed to first stage < 0.1%, oil contaminant concentration in feed to second clean-up stage 5–10%, well-head oil concentration in feed to wet oil concentrator 5–50%
Orientation	Fixed, 'g' important	No limitation, lateral acceleration up to ~ 0.1 'g' on floaters unimportant

Southampton bi-cone design, which had twin tangential inlets to produce a linear core. The right-hand side illustrates a typical later development with a single 180° wrap-round involute inlet and a curved wall. Note the absence of a projecting vortex finder, since there is no loss of oil in any short circuit flow in the end wall boundary layer.

Both the clean-up and concentrator units use the same wall profile but the latter has a larger overflow (or reject) port.

Later systematic work by Young (1994) came up with similar proportions.

Stronger swirl increases the acceleration field, but also raises the pressure drop and too much swirl seems to increase vortex instability and shear. Using a swirl number S ($S = \pi D_R X_i (2A_i)^{-1}$, where A_i is the total inlet area measured at a point where the flow is normal to the radius from the hydrocyclone axis to the centroid of the area, X_i , and D_R is a reference diameter of the hydrocyclone), the range of values for *de-oilers* is typically 7–11 or more usually 8–10. The reference value D_R for the bi-cone design is at the junction of the two cone angles (see Figure 1), and for a curved wall at, say, the point where the tangent is at about 10° to the cyclone axis.

The axial pressure gradient near the centre line is *not* zero: see section on pressure drop later.

De-oiling hydrocyclones have shown a range of sizes but there are no large units as for solid-liquid separators, since large droplets do not exist and thus no requirement for units with a relatively small acceleration field. Size is a compromise, taking into account the factors shown in Table 3. Early installations showed D_R values rising from about 30 mm to

70 mm, but more recently this has tended to drop back to about 15–30 mm.

Installation

Unlike solid-liquid units, clean-up or concentrator hydrocyclones have hitherto almost always been installed in pressure vessels, as shown schematically in Figure 2. This allows easy fabrication of individual units (sometimes called liners) from relatively thin walled material and reduces the number of connections to be made. Several assemblies complete with instrumentation and controls are built into a skid. Some larger units have serious vibration at very high flows so that a mid-length damper is built in.

The overflow or reject stream, being a small proportion of the feed, is readily incorporated into a manifold which may double up as a mounting plate.

Though series operation is possible and has been laboratory proven, in the field the use of a single stage with many units in parallel has hitherto been worldwide. Even though the turn-down ratio (comparison of maximum and minimum usable flowrates) for an individual unit is limited – see later discussion of the influence of feed flowrate on separation – the installation of units in banks which can be valved out in turn, allows overall turn-down ratio of about four for two banks, eight for three banks and so on.

Increased cleaned water throughput of an existing installation can be achieved by the addition of more hydrocyclone units.

Apart from modularity and improved separation, clean-up hydrocyclones have other advantages over the equipment formerly used such as induced gas

Figure 1 Hydrocyclone proportions. (left) Southampton University bi-cone design; (right) Typical later industrial development.

flotation (IGF) plant or gravity separators with plate packs. The installed size and weight of hydrocyclones has only been found to be about 10% of the older plant. Since hydrocyclones have negligible free surface effects they are insensitive to orientation and the motion of floating equipment. Unlike IGF they have no large requirement for chemicals and their cleaned underflow water does not require subsequent processing apart from occasional flocculant addition to reduce oil content below the legal limit.

As the unit residence time is only 1–2 s the hydrocyclones cannot cope with a slug of oil. Any zones of high shear upstream from these de-oiling hydrocyclones will reduce the size of oil droplets, thus worsen-

ing the separation efficiency. New installations can largely alleviate this problem by re-design to re-position flow-control valves to come after a hydrocyclone rather than upstream from it.

Performance

Though variables will often interact, for convenience their effects are discussed separately.

Separation Efficiencies

To achieve the purity required of the underflow stream from a clean-up unit, its output rate is usually

Table 3 Factors influencing the size of de-oiling hydrocyclones

Factor	Influence
Flowfield Reynolds Number, $u_i D_i/\nu$	In early development its perceived influence on separation suggested larger units. Now ignored
Pressure drop	Larger units have higher pressure drop, for the same peak radial acceleration field. Even though the reservoir pressure is often high enough to remove the need for pumps this factor tends to limit size
Separation of smaller drops *	As the hydrocyclone size reduces to a D_R of approximately 20 mm improved separation efficiency of droplets smaller than about 15 μm is achieved
Avoidance of excessive shear	For D_R values below about 10 mm experimental observation suggests that high shear causes droplet break-up and consequent loss of separation efficiency
Cost for a given flow rate	Favours few, larger units if cost for unit alone is considered
Packing density*	Units are normally installed in a pressure vessel. Higher overall throughputs can be achieved for a fixed volume pressure vessel fitted with many smaller rather than fewer larger units. This favours reduced cost for complete assembly.

*Generally dominant factors in current practice.

restricted to about 98% of the feed stream rate. This can result in the overflow reject stream having a significant water content; fortunately the oil droplets in this stream coalesce readily causing the oil and water phases to separate easily. The oil may then be pumped into an oil storage vessel or delivery line.

The inability of hydrocyclones to achieve perfect phase separation in a single step has previously been noted by Bradley (1965).

For an oil-water hydrocyclone operating in the concentrator mode, the yield of oil in the overflow product stream is the principal criterion.

Definitions for purity and yield follow below.

The performance of any separation unit is usually defined in terms of the fractional recovery η

of the valuable product and its purity in the product stream ε . For the clean-up units the fractional recovery η_0 is however defined by the fraction of oil in the feed which appears in the reject (overflow) stream, and ε_u for this operation is defined in terms of the oil (waste) content of the product (underflow) stream:

$$\eta_0 = \frac{Q_o \times C_o}{Q_f \times C_f}$$

and

$$\varepsilon_u = 1 - \frac{C_u}{C_f}$$

**Figure 2** Pressure vessel installation of oil-water hydrocyclones. (One unit shown.)

if the split ratio R_f and its complement F are defined by $R_f = Q_u/Q_f$ and $F = Q_o/Q_f$.

Then a relationship between the fractional recovery parameter η_0 and the underflow purity ε_u follows:

$$\eta_0 = 1 - \frac{Q_u \times C_u}{Q_f \times C_f}$$

thus $\eta_0 = 1 - R_f \times (1 - \varepsilon_u)$.

One bonus for the de-oiling duty is that the produced water, i.e. brine, is often warm. Higher temperature is beneficial as the water viscosity is reduced and the differential density increased. Possible problems arising solely from the elevated temperature, with reduced interfacial tension and easier distortion of oil drops as they are less viscous, seem unimportant. Thus values of ε_u of 0.99 or even 0.999 have been obtained, even though the differential density may only be 100 kg m^{-3} with a mean drop size $20\text{--}30 \text{ }\mu\text{m}$.

Generalized prediction of ε_u and η_0 is very difficult. Apart from the practical difficulty of predicting the feed drop size distribution, droplet break-up is influenced by interfacial tension. In the complex liquid mixtures of crude oil and produced water, interfacial tension is influenced by surface-active agents whose presence and effects are difficult to determine.

Correlation of experimental results could ideally use the Stokes Number ($St = 2Q_f\Delta\rho d^2/\pi 9D_R^3\mu$, where $\Delta\rho$ = differential density, d = characteristic droplet diameter, μ = viscosity of the continuous fluid). Strictly, this only applies to dilute dispersions with Stokesian flow with a droplet at a Reynolds Number below unity. The major problem which tends to restrict usage to laboratory investigations is in the determination of d . This is usually taken as the d_{50} diameter of a droplet that has an equal chance of reporting to underflow or overflow, but in most applications it is impractical to measure it.

Influence of Feed Characteristics

Flow rate At low flow rates the tangential velocity is too low to generate an adequate inward radial acceleration. This is reflected in the field results of Meldrum *et al.* in 1987 which have been converted from tabular results to the plot in Figure 3. These show sharply decreasing values of ε_u for a 60 mm D_R hydrocyclone on the Hutton field and for a 35 mm D_R hydrocyclone on the Murchison field for feed flows below $\sim 100 \text{ L min}^{-1}$ and 60 L min^{-1} , respectively.

Figure 3 also shows rapid falls in ε_u values for the 35 mm Murchison unit for feed flows above

Figure 3 Field results: separation efficiency (ε_u) vs flow rate (Q_f). Calculated from Meldrum *et al.* data.

$\sim 200 \text{ L min}^{-1}$ and for the 60 mm Hutton unit above $\sim 425 \text{ L min}^{-1}$, which reflects a split ratio falling below the critical value. This is discussed fully later but essentially as flow rate rises the outlet pressures fall, and as the overflow outlet is at the lower pressure, a stage is reached where the overflow stream is so diminished that oil can only leave via the underflow.

The turn-down ratios illustrated by Figure 3 are 3 for the Murchison unit operating on a feed concentration $C_f < 0.1\%$ and 4.5 for the Hutton unit, but other fields with a larger driving pressure available have achieved values up to about 7. Pumped installations or oilfields with lower reservoir pressures might fall to about 2, for a single unit.

A plateau region separation efficiency is usual. Higher flow rates raise the acceleration field but, residence time falls, turbulent re-mixing rises and if interfacial tension is low droplet break-up may become significant. Within the plateau region, rapid transients in flow rate should not reduce separation efficiency appreciably.

Oil-water ratio Over a wide range of oil concentrations clean-up and concentrator hydrocyclones are considered to act as a flow divider, i.e. ε_u remains constant and C_u will rise in proportion to C_f if droplet size remains constant, however field results show this to give a pessimistic view as droplet sizes rise with oil content. This means that C_u may even remain constant as C_f rises.

As C_f rises the split ratio may need to be raised also. For clean-up the value of F is often maintained at 2–3%, but a rational control strategy is discussed later. In concentrator operations when C_f rises to

Table 4 Transient oil separation performance

d_f μm	ε_u Steady-state	% drop (ε_u steady state – ε_u transient)	
		5 s injection	2 s injection
50	0.93	0	1
17	0.53	4	6

d_f = mean feed drop size, BP Forties oil in cold tap water, C_f steady state $\sim 500 \text{ mg kg}^{-1}$.

5–10% the ratio F/C_f may be conservatively maintained at 2. This means the overflow stream is 50% water; for it to be, say, 70% oil (favourable result) F/C_f falls to about 1.4. A moderate transient increase in oil content, provided the F/C_f ratio remains satisfactory, has very little effect on ε_u . Table 4 shows results for a short-lived oil pulse, obtained with on-line oil content measurements compared with steady-state results.

A larger increase in C_f , but still within the acceptable range, may show a rise in ε_u if droplet size has also risen. Any further rise in C_f will exceed the capacity of the overflow and ε_u will fall substantially when F/C_f falls below about 1.2.

Droplet size Like all separation devices based on differential density, in a hydrocyclone, reduction in droplet size will give poorer results. An acceptable minimum value for d_f under favourable conditions may be as low as 5–10 μm (elevated temperature, $\Delta\rho > 150 \text{ kg m}^{-2}$, adequate interfacial tension), however the usual acceptable minimum of the feed droplets is 15–20 μm .

Droplets of 20 μm are less vulnerable to low values of interfacial tension in promoting break-up than larger ones. However, the presence of surfactants that drastically lower interfacial tension will almost certainly reduce the effectiveness of hydrocyclone separators, as shown by Colman, Thew and Corney at the First Hydrocyclone Conference (Cambridge, UK) in 1980.

In laboratory work, grade efficiency curves d_f vs ε_u have been obtained as for solid-liquid hydrocyclones, but because of the considerable difficulties in obtaining representative samples and in measurement such curves are seldom available in the field. When sampling, both isokinetic conditions and avoidance of droplet break-up are necessary and gas bubbles may complicate interpretation. A suitable technique was discussed by Colman, Thew and Corney.

Free gas Until fairly recently most clean-up hydrocyclones were installed downstream from three-phase separators. This means that the free gas content of the hydrocyclone feed was a fairly minor constituent. As

a result any gas core was relatively small in diameter. Because of the significant axial pressure gradient at the centre line this gas leaves with the overflow (oil-rich) stream.

Provided the gas content of the feed is reasonably invariant with time, laboratory tests have demonstrated that oil separation is little affected up to a threshold of 20–30% by volume free gas. This figure relates to conditions at the hydrocyclone entry. Field experience has generally confirmed this satisfactory picture except when the gas flow exhibits significant slugging. An entering gas slug does not have the angular momentum to maintain rotation of liquid and with the breakdown of inward radial acceleration, separation performance falls sharply. Amongst the thousands of units in service such a loss of performance is uncommon.

One consequence of appreciable gas leaving via the overflow is that it reduces the area for liquid to an annulus in the overflow exit port. This changes the relationship between the pressure drop and flow rate for the overflow liquid thus adversely affecting the control.

With the pressure drop in the hydrocyclone, some evolution of dissolved gas would be expected. This does occur but is too slow to be appreciable within the hydrocyclone and is manifest downstream from it, being most noticeable in the overflow stream. The evolving gas has been used to achieve post-cyclone separation of some more very fine drops in a suitable vessel possibly because the evolving gas bubbles nucleate on the oil droplets. In terms of Henry's Law the mass of gas coming out of solution in the overflow, will be proportional to $Q_o \times H (p_f - p_o)$ where p_f is the upstream feed pressure, p_o is the downstream overflow pressure and H is Henry's constant. However, the volume evolved will also depend inversely on the absolute pressure and in any case Henry's Law gives a maximum value as it relates to equilibrium conditions.

Solid particles Crude oil-brine mixtures commonly contain small amounts of reservoir solids. This problem is growing as more fields have larger produced water contents and it is made worse by the trend to produce from unconsolidated formations. The amount may range from a few hundred mg L^{-1} to about 10 g L^{-1} in worst cases. The solids may be water-wetted or oil-wetted, both usually report to the underflow unless the oil-wetted solids are very fine, in which case they may tend to be neutrally buoyant. In practice the overflow stream very seldom contains solids. Overflow blockages are rare and when they do occur they are usually associated with debris left in the system at installation or after maintenance.

Erosion, if it occurs, is usually restricted to the inlet region where velocities are higher. The use of harder materials, for example Stellite, in the inlet region has allowed long periods of satisfactory operation. A number of installations have run continuously for five years or more.

A development of the last 2–3 years is the arrival of de-sanding hydrocyclones installed ahead of the de-oiling units. These have been used prior to the choke with a containment vessel to withstand the very high pressure. Both relatively large units in appropriate steels and smaller ceramic units are entering service.

In off-shore fields the water in the oil–water mixtures may be quite corrosive, particularly if it is sour (containing H_2S). This has necessitated the use of alloy steels in the fabrication of the clean-up hydrocyclones. However, particularly for low cost, low flow land-based installations, cheaper materials may be satisfactory. Polyurethane units, possibly in a carbon steel casing or even bare are on the threshold of commercial usage.

Pressure Drop (the Cost Implications for Separation)

As in solid–liquid hydrocyclones, pressure drop $\Delta p \sim Q_f^m$ where $2.1 < m < 2.2$. In dimensionless terms defining:

$$\text{Euler Number } N_{Eu} = \frac{\Delta p}{\frac{1}{2} \rho u_f^2}$$

$$\text{Reynolds Number } N_{Re} = \frac{u_f D_i}{\nu}$$

where $u_f = Q_f/A_i$ and the inlet port diameter $= D_i$ (for multiple or noncircular inlets D_i is the diameter of the circular port with equal A_i).

Leads to the dimensionless relationship

$$N_{Eu} \sim N_{Re}^n$$

where

$$0.1 < n < 0.2$$

The use of u_f in terms of Q_f and A_i will be reflected by changes in the swirl number S .

Values of ρ and ν are based on arithmetic averages of the mixed liquids. Uncertainty in the value of the kinematic viscosity ν is not serious due to the small value of n . Typical Euler Number values are in the range 10–20 and do not seem to be affected by variations in C_f .

The de-oiling hydrocyclones have a substantial pressure gradient along the hydrocyclone axis not present in solid–liquid hydrocyclones with an air core. Thus pressure drop between the feed and the

overflow Δp_{fo} is greater than the pressure drop between the feed and the underflow Δp_{fu} , the relationship between the two being variable and set by external valves. The ratio between the two is important for control and optimization and this pressure drop ratio ($PDR = \Delta p_{fo}/\Delta p_{fu}$) varies with split ratio, R_f and also its complement F . Δp_{fo} has two principal components – one due to the radial pressure gradient and the other arising from the velocity through the overflow port. The radial pressure gradient and Δp_{fu} are both proportional to the u_f^2 and S , since $u_f = Q_f/A_i$. For a fixed geometry the $PDR = B_1 + B_2 \times F^2$ where B_1 and B_2 are constants, where $B_1 = f_1(S)$ and $B_2 = f_2(S, A_0^{-1})$. The oil concentrated overflow rate is regulated by using a fixed PDR value as set-point.

Pumped installations In younger oilfields the driving pressure stems from reservoir pressure. In older fields where pumping is necessary, this represents a cost. To reduce droplet break-up a low shear positive displacement pump should be used, however centrifugal pumps have proved satisfactory provided their speed is not too high and the duty is not too far from their best efficiency point. Fields with electrical submersible pumps have utilized de-oiling hydrocyclones satisfactorily.

Operator Control

For water clean-up units the PDR set-point is usually in the range 2–3 but for concentrators, with their larger overflows, values below 1.5 may be set. A simplified control layout is shown on Figure 4. The effectiveness of the control is restricted to some extent by the relative sizes of the underflow and overflow exit ports.

The PDR is a weak function of the feed Reynolds Number ($N_{Re} = u_f D_i/\nu$), see Figure 5. This dependence is usually ignored.

Critical split ratio (F_{CRIT}) At low oil contents it is desirable to reduce F thereby reducing the amount of the overflow stream. But below a critical value F_{CRIT} the axial pressure gradient near the centre line is inadequate to sustain the reverse flow. Though oil still gathers in the vortex core it is unable to reach the overflow outlet, becomes remixed near the inlet and leaves via the underflow so ε_u falls sharply. The effect is illustrated on Figure 6. F_{CRIT} rises with an increase in the diameter D_o of the overflow port and is therefore higher for concentrator units. Though extremely small overflow outlets will permit very small F_{CRIT} values, they are impractical as the smallest upset is too much for them to handle.

Table 5 summarizes the factors to be considered in control of the split ratio via the easily measured

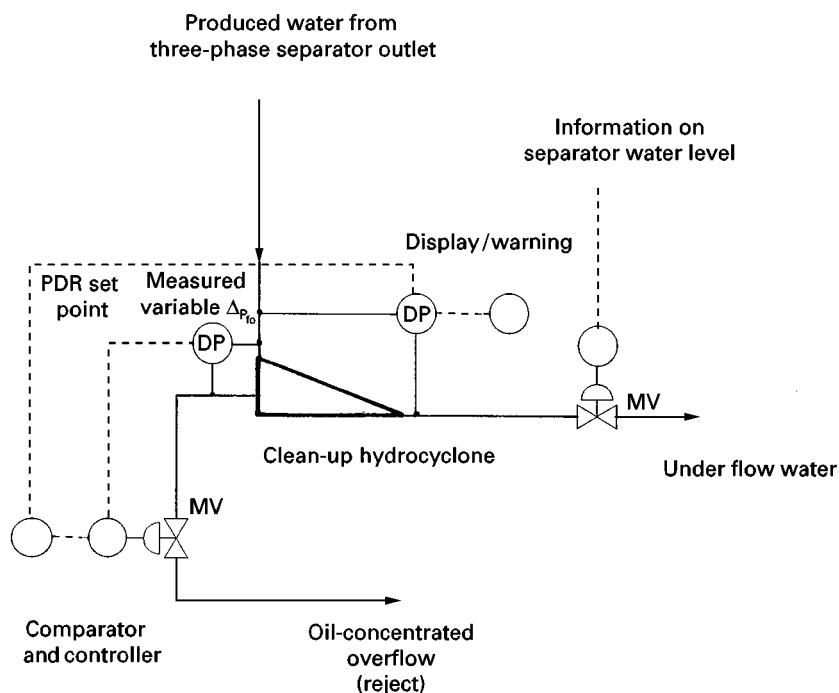

Figure 4 Simplified control layout.

variable, PDR. Hydrocyclone manufacturers will advise on the size of the overflow outlet. It may require enlargement during the life of an oilfield.

Cost Comparisons

Cost data are sparse but some information produced by BP about five years ago has been recast on Table 6 in terms of ratios. The flow rate used for deriving the information was applicable to a field producing about 16 000 m³ per day of oil.

Figure 5 Pressure drop ratio (PDR) vs inlet Reynolds Number. Southampton University laboratory results and field results deduced from the data of Meldrum *et al.*

Table 6 shows that both the capital and running costs increase in the sequence hydrocyclone-IGF-filter/coalescer-centrifuge. Hydrocyclones also produce the most compact plant and are the least sensitive to orientation or lateral acceleration as encountered in installations on a floating base.

Future Developments

In 1979 an oil industry task force recommended plate pack gravity separators or IGF for produced water clean-up. Six years later the first large hydrocyclone installation – about 15 m³ min⁻¹ – was operating successfully in the North Sea, so the points below relate only to the immediate future, perhaps prior to 2003.

- Improving oil separation (in hydrocyclones) means removing smaller drops. There is probably limited scope for further optimizing geometry, though the claims for computational fluid mechanics (CFD) in rapid optimization are likely to become valid in a year or two. (Adequate representation of turbulence in confined swirling flow has proved difficult.)
- For new systems and even for some retro-fits, there is often room for worthwhile improvement by reducing shear upstream of the hydrocyclones or re-locating them. The resulting larger drops ease the separation task.

Figure 6 Separation efficiency (ϵ_u) vs complement split ratio (F). The collapse in separation consequent on too low an overflow is shown.

- If the split ratio needs frequent adjustment, a variable area overflow (two values would be adequate) simply controlled would be very useful. Laboratory tests have shown that this is readily feasible but moving parts are still not readily accepted, as they are associated with reduced reliability.
- As the cost of dealing with produced water mounts, economic/technical studies have strongly suggested hydrocyclone installation at the bottom

of the wellbore, 'downhole'. If the geology is suitable the water could be re-injected in adjacent strata. Preliminary trials using electric submersible pumps (ESP) (some concepts suggest two) have shown and are showing considerable promise. Access after installation is costly so there are problems in control and reliability, though ESP speed variation is proven. Reduced standards of separation may still be acceptable. A halfway stage to use pre-choke hydrocyclones on the sea bed is also being investigated.

Table 5 Factors affecting PDR

Factor	Correction to PDR	Comment
$F < F_{\text{CRIT}}$	Increase*	Oil is lost in underflow, $\epsilon_u \rightarrow 0$
$F/C_i < 2$	Increase*	Some oil lost to underflow (conservative criterion)
Excessive free gas in underflow	Increase*	Effective overflow area for liquids is reduced. Condition may be difficult to detect
F too high	Reduce	Δp_{io} excessive
F too high	Reduce	Too much water in overflow stream

*Opening the valve in the overflow raises the flowrates hence increasing PDR.

Table 6 Relative cost for clean-up plant ($16\,000\text{ m}^3\text{ d}^{-1}$)

Plant type	Capital cost	Running cost	Oil separation performance [†]
Hydrocyclones*	1.0	1.0	3
Induced gas flotation	1.1	1.1	4
Filter/coalescer	1.3	1.6	2
Centrifuge	4.6	4.0	1

*Capital cost is $6\text{--}7 \times$ annual running cost based on data from several North Sea fields with installations ~ 10 years old.

[†] Ranking order for oil content in cleaned flow with identical oil content and mean drop size in the feed; 1 is best.

- De-sanding hydrocyclones are now being installed upstream from the choke in some fields. There could be an energy saving if de-sanding and de-oiling could be performed in a single unit, but simultaneous optimization of both functions is unlikely. A successful laboratory research project has been reported in France, but initial field trials in West Africa were disappointing.
- Heavy oils, i.e. those with a higher density and viscosity, appear unpromising for cyclonic separation processes. Nevertheless success has been reported for commercial de-oiling units used in the concentrator mode in trials in western Canada.
- Feasibility studies and preliminary field trials are in progress on integrated de-watering plus de-oiling cyclonic separation and/or de-sanding plus de-oiling. The attraction is an ultra-compact plant suited particularly to floating installations. Though de-watering units have not yet met with widespread success, the impending arrival of compact, robust electrocoalescers to raise water droplet size prior to separator entry, could transform the situation.
- With success in dealing with petroleum it is surprising that applications to edible oils, which are about 10 times more valuable, have yet to materialize. Laboratory trials have been very satisfactory. Not only is lost oil a revenue drain but it generates a potential environmental hazard.

Introduction

Dissolved air flotation (DAF) is a solid-liquid separation process for the removal of fine suspended material from an aqueous suspension. The basic principle underlying DAF is Henry's law, which gives the solubility of air in water. According to Henry's law, the solubility of air in water is directly proportional to its partial pressure. A supersaturated solution of water is produced using high pressure in a saturator. The bubbles are generated by the pressure release of this water stream. These bubbles attach to

suspended material present in the aqueous stream, causing them to float to the surface, where they are collected as floc.

DAF can be carried out by vacuum or pressurized methods. In the vacuum flotation method the water to be treated is saturated with air at atmospheric pressure. The bubbles are produced by applying a vacuum to the flotation tank, releasing the air as fine bubbles. The vacuum flotation process has several disadvantages. These are (a) the amount of air available for flotation is limited by the vacuum achievable, (b) it is a batch process, and (c) it requires special equipment to produce and to maintain high vacuum. These disadvantages limit the application of vacuum flotation and it is only used in wastewater sludge thickening.

The pressure flotation process is the most widely used DAF technique. High pressure water is saturated with air. This pressurized water forms small bubbles when injected into water at atmospheric pressure. Three types of pressurization processes can be used in DAF: full flow, partial flow and recycle flow pressurization. The entire inlet stream is pressurized in full flow pressure DAF. It is commonly used when the wastewater contains large amounts of suspended solids and the pressurization process does not affect the treatment efficiency of the system. Partial flow pressurization is used where the wastewater contains moderate to low concentrations of suspended solids. In the recycle flow pressurization system, 10–25% of the clarified effluent is recycled through a pressure vessel to the flotation tank. The flocculation process is not disturbed in the recycle flow system because of intense mixing and pressurization as clear water is pumped. A recycle flow system is cost-efficient because it pressurizes only part of the water, thus requiring less compressor power. Recycle flow pressure flotation is the best-suited system for most DAF applications.

DAF is an effective alternative to sedimentation. The advantages and disadvantage of DAF relative to sedimentation are as follows:

Advantages

1. Clarification rates are higher in DAF, resulting in smaller flocculation tank volumes.
2. More concentrated sludge solids are produced in DAF than from sedimentation.
3. DAF uses lower amounts of coagulants and flocculant aids.
4. Oxygenation effects in DAF reduce odour problems.
5. DAF provides better removal of low density particles and algae, which can plug filters.

Disadvantage

1. DAF processes are more costly to operate and maintain than sedimentation processes.

Process Description

A schematic diagram of a DAF process for wastewater treatment is shown in Figure 1. Its essential elements are a flocculation tank, a flotation tank, an air compressor, an air saturator, a recycling pump and a hydrosweep system. The wastewater is pumped to the flocculation tank after being treated with coagulant/flocculent agents such as aluminium sulfate. A portion of the clarified effluent is recycled for pressurization. Compressed air is introduced into the discharge stream of the recycle pump, and the water is saturated with air at high pressure. The pressurized water stream is introduced to the flotation tank through nozzles, where fine bubbles (20–100 μm) in diameter are formed. The bubbles attach themselves to suspended solid particles, causing the agglomerates to float to the surface of the tank. The float can be mechanically skimmed from the surface, and the clarified water is taken from the bottom of the flotation tank.

Principles of Dissolved Air Flotation

DAF facilities are composed of the following four principal steps:

1. coagulation and flocculation prior to flotation
2. bubble generation
3. bubble–floc collision and attachment in the mixing zone
4. rising of the bubble–floc aggregates in a flotation tank

Coagulation and Flocculation Prior to Flotation

Coagulation and flocculation are often considered as a pretreatment step in DAF processes. Favourable

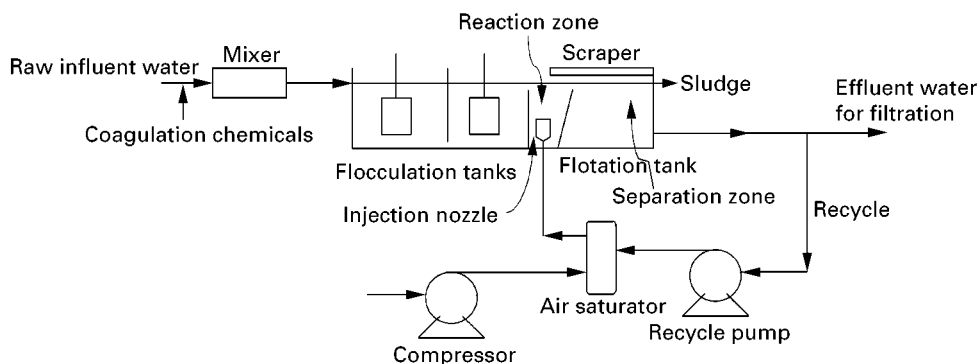

Figure 1 Schematic diagram of the dissolved air flotation process for water treatment.

conditions for bubble attachment to particles requires coagulation conditions that reduce particle charge and produce hydrophobic particles. Coagulant dosages and pH conditions that satisfy these criteria depend on the coagulant type and raw water characteristics, including particle concentration, hardness, and concentration and type of natural organic matter (NOM). Unlike in sedimentation, large floc particles are not needed in DAF. Flocculation tanks are designed to produce strong flocs with particle size distributions of 10–30 μm and short flocculation times, in the range of 10–15 min.

Bubble Generation

Small air bubbles, 100 μm or less, are formed by injection of supersaturated pressurized recycle water into a flotation tank using specially designed nozzles. The process of bubble formation involves two steps: nucleation and growth. During the first step the large pressure difference across the nozzle produces bubble nuclei spontaneously. Air bubbles grow at a fixed number of nucleation centres due to air transferred from the water. As the excess air is transferred from the dissolved to the gas phase, the bubbles grow in size. Additional bubble growth may occur as the bubbles rise due to a decrease in hydrostatic pressure or coalescence.

Measurements of bubble sizes for DAF systems indicate that bubbles maintain a steady-state size range of 10–100 μm . A reasonable estimate of average bubble diameter is 40 μm . The steady-state size depends on the saturator pressure and the injection flow rate. The injection flow must provide a rapid pressure drop and be sufficient to prevent back-flow and bubble growth on pipe surfaces in the vicinity of the injection system. To ensure small bubbles, pressure differences (saturator gauge pressures) of 400–600 kPa are recommended.

Bubble Floc Collision and Attachment in the Mixing Zone

There are three possible mechanisms for forming aggregates of bubbles and particles:

1. entrapment of preformed bubbles in large floc structures (floc size much larger than bubble size scale)
2. growth of bubbles whose nuclei formed on particles or within flocs
3. particle collision with adhesion to preformed bubbles

For DAF processes, the third mechanism is the most important.

Classically, the contact angle between the adsorbed bubble and particle has been used to characterize the extent of bubble–floc adhesion. Here the contact angle must be finite and large enough that the energy of adhesion of water to the solid particle is less than the energy of cohesion of water. A larger contact angle indicates both hydrophobicity and good adhesion. The magnitude of the contact angle, however, depends on the size of the bubbles and particles. A different view of particle–bubble attachment of colloidal particles by small bubbles is that a finite contact angle need not form. In this heterocoagulation model, the stability of charged particles and bubbles is described. Attachment requires reduction in electrical charge interactions and attraction by London–van der Waals forces as particles are transported to bubble surfaces.

Both the contact angle and the heterocoagulation models predict experimentally observed trends that two conditions are necessary for favourable flotation: charge neutralization of the particles and production of hydrophobic particles. Bubble attachment to particles requires hydrophobic particle surfaces or hydrophobic regions on the particles. For many particles, hydrophobicity can be increased by reducing the negative charge. Other particles, such as freshly precipitated or amorphous $\text{Al}(\text{OH})_3$, have polar surface groups that make them hydrophilic. This hydrophilic effect may be reduced by charge neutralization, but aluminium hydroxide particles have a polymolecular coating of water which hinders bubble adhesion.

Rising of the Bubble–Floc Aggregates in a Flotation Tank

Following bubble attachment and reduction in particle density, particle–bubble agglomerates rise to the surface of the flotation tank in the separation or clarification zone. The rise velocity of the particle–bubble agglomerate may be calculated using Stokes law.

DAF Modelling

The design and operation of DAF facilities has largely been based on experience and results from pilot-plant studies. In recent years, a conceptual model of DAF has been developed, based on a single collector collision theory in laminar flow conditions (SCC model). A kinetic model has also been presented, based on the population balance model of bubbles and flocs in a turbulent flow condition (PBT model).

For modelling purposes, DAF processes can be divided into two zones: reaction zone (regions where

the saturated recycle flow is introduced) and separation zone.

Reaction Zone Modelling

For the reaction zone efficiency (dN_{fl}/dt), defined as the reduction of number of primary particle flocs with time, floc and bubble size (d_{fl} and d_b) and concentration are defined as relevant process parameters:

$$dN_{fl}/dt = -(3/2)(\alpha_{pb}\eta_T)(\Phi_b\nu_b N_{fl})/d_b \quad [1]$$

where α_{pb} = particle bubble attachment efficiency; η_T = total single collector efficiency; d_b = bubble diameter; ν_b = bubble rise velocity; N_{fl} = floc number concentration; Φ_b = bubble volume concentration.

Particle (floc)–bubble interception is considered to be the most relevant kinetic mechanism for DAF efficiency, depending on the floc and bubble size (d_{fl} and d_b) and incorporated in η_T . This term also considers floc–bubble collision mechanisms related to Brownian diffusion, settling and drag.

A summary of these parameters, their dependence on the system variables and desirable operational conditions is given in Table 1.

Separation Zone Modelling

Assuming laminar flow conditions, the efficiency of the separation zone, ν_{flb} (defined as floc–bubble

agglomerate rising velocity), is defined by the floc–bubble agglomerate size (d_{flb}) and density (ρ_{flb}) (eqn [2]). These are dependent on the floc size–density ratio and concentration, and the size and number of bubbles comprising the floc–bubble agglomerate:

$$\nu_{flb} = g d_{flb} (p_w - p_{flb}) / 18 \mu \quad [2]$$

Eqn [3] represents a necessary prerequisite for efficient DAF, ν_{os} being the DAF overflow rate and m being the fraction of DAF tank dead space:

$$\nu_{flb} > \nu_{os} / (1 - m) \quad [3]$$

Applications of Dissolved Air Flotation

DAF is best applied to remove materials that normally settle slowly, persist in remaining in suspension or have a tendency to float. Prior to the 1960s it was mainly utilized in the area of mining and metallurgical industries. Now, DAF finds numerous applications, e.g. mineral processing, water purification, wastewater treatment, waste sludge thickening, wastewater reclamation, recycled paper de-inking, and many more. It is widely used for drinking water purification in many Scandinavian countries, South Africa, the Netherlands, the UK and others. In drinking water clarification, DAF has been applied in combination with flocculation for the removal of

Table 1 Summary of conceptual reaction zone model parameters

Parameter	Dependence	Comments
<i>Pretreatment parameters</i>		
α_{pb} (particle–bubble attachment efficiency)	1. Particle–bubble charge interactions	1. Favourable flotation; requires reduction in particle charge and hydrophobic particles
	2. Hydrophilic nature of particles	2. Increase α_{pb} to 1: optimum coagulation and charge neutralization
N_p (particle number concentration)	1. Raw water quality	1. Concentration and size of particles; concentration of NOM
	2. Coagulant type and conditions	2. Coagulants may add particles
	3. Flocculation time	3. Flocculation may reduce N_p and increase d_p
<i>Reaction zone–flotation tank</i>		
η_T (total single collector efficiency)	1. Particle–bubble collisions from diffusion and interception	1. Increase η_T : produce floc size of tens of μm
	2. Minimum η_T for d_p of $\sim 1 \mu\text{m}$	2. Short flocculation times
d_b (bubble diameter)	Controlled by pressure difference across nozzle and injection flow	1. Desire microbubbles: range 10–100 μm , median 40 μm ; smaller bubbles: better performance
		2. η_T varies as d_b^{-2} ; rate of collection of particles varies as d_b^{-1}
Φ_b (bubble volume concentration)	1. Saturator pressure	1. Increasing Φ_b increases N_p : more bubbles for collection of particles
	2. Recycle ratio	2. Increase Φ_b : more bubble volume for reducing floc density

algae and humic substances. The first water treatment plant based on the DAF process was established in South Africa in 1969. Since then it has received worldwide attention for research and development on all aspects of DAF.

The first DAF plant in the USA was set up at the Millwood water treatment plant in Westchester county (35 miles north of New York city) in August 1993. Now, several other plants based on DAF are operating or are under study in the USA. It is postulated that DAF is an emerging technology in the USA that will become more important because of existing and proposed regulations that require filtration of surface waters and increased removal of protozoa cysts such as *Cryptosporidium* and *Giardia*. Large scale pilot-plant trials of water treatment have been carried out in the UK for removal of *Cryptosporidium* using DAF. Well-operated chemical coagulation-based treatment using DAF should be capable of achieving 99% removal of *Cryptosporidium* oocysts.

DAF is also used in the forest industry, food-stuff industry, meat-processing industry, seafood industry, potato processing, pulp and paper industry, petroleum industry, poultry industry, producing refined sugar from raw juices, separation of grease, oil, fibres and other low density solids, chemical processing plants, storm water cleaning, and other similar industries.

Future Trends

There is great potential for DAF. Its use has been limited due to lack of knowledge of the process by users, designers and other regulatory agencies. The

design and operation of DAF methods are currently tested on empirical data and data from costly and time-consuming pilot-plant models. More information is needed on the performance, designs and costs of the DAF process.

Introduction

Mineral separation by flotation is based on the selective levitation and separation of mineral particles by gas bubbles. This is carried out by the selective conversion of the surfaces of the minerals to be floated

from their typical hydrophilic nature to hydrophobic, to which the gas bubbles may attach to effect the levitation. This conversion is usually achieved by the selective attachment of collectors to the surface of the mineral or by natural processes; an example of the latter is the formation of elemental sulfur or a metal-deficient sulfide layer on sulfides.

Typical collector agents are organic substances consisting of an ionic, i.e. hydrophilic, end that attaches to the mineral and a nonionic hydrocarbon end that creates the hydrophobicity of the mineral surface. A widely used collector in selective sulfide flotation is the xanthate ion (O-alkyldithiocarbonate, ROCS_2^-).

Most of the sulfide minerals are electronic semiconductors or electrically conductive. This implies that the reactions required for the creation of a hydrophobic surface on sulfides may be electrochemical. For example, the xanthate ion may be oxidized at an anodic area of a local cell on the mineral surface to form hydrophobic dixanthogen:

The corresponding reduction reaction is the catalytic reduction of oxygen. Apart from this type of electrochemical reaction, electrochemical interaction between dissimilar sulfide minerals of different rest potentials occurs when there is electrical contact between them in a sufficiently conductive electrolyte, and this is of a galvanic nature. For contact of this nature to occur the various sulfides must be either present in composite particles, i.e. middlings, or be brought into such frequent collision contact in the flotation pulp, that significant electrical charge transfer can take place. In the laboratory these phenomena can be studied by electrically connected mineral electrodes, or stirred/fluidized beds made up of sulfide minerals only. Although these laboratory methods indicated significant electrochemical interaction, studies conducted at the authors' laboratories on simulated mineral feed of realistic plant composition showed no significant charge transfer. This was possibly due to the complexity of the flotation pulp chemistry, which makes it difficult to distinguish between the contribution of chemical and electrochemical processes to overall plant performance.

Theory and Principles of Electrochemical Interaction between Mineral Species

Reactions on mineral surfaces in which there is a change of oxidation state for the species involved are generally electrochemical in nature. This adds to the complexity of multi-mineral systems, in the sense that, apart from interactions through a common aqueous phase, by for instance dissolution-precipitation reactions, galvanic interactions through electrical contact between minerals must be considered also. Galvanic interactions between minerals will cause the more inert mineral to act predominantly as cathode, and reduction of dissolved oxygen would typically occur on its surface. This will stimulate anodic counter-reactions such as the oxidation of xanthate to dixanthogen or metal xanthates and that of metal sulfides to metal-deficient sulfides or elemental sulfur,

all of which will promote hydrophobicity on the surface of the more reactive mineral.

Similarly, contact of a less reactive sulfide mineral particle with more reactive steel, generated in abundance by industrial grinding operations, in the form of loose particles or layers smeared onto the mineral surfaces, may depress the mixed potential of the galvanic couple to such an extent that the oxidation reactions necessary for the hydrophobization of the sulfide surface will be slowed down. In extreme cases, reactions may become thermodynamically impossible.

In the following sections the role of electrochemical interactions in the separation of complex sulfide ores will be further explored. Particular attention will be paid to the use of pulp potential as a monitoring and control tool and the role of electrochemical reactions in the development of hydrophobicity.

Mixed Potential Theory

The interaction between collector reagent and mineral takes place at the mineral-solution interface. For ease of reference, and in view of the vast body of investigative work done on it, our discussion will focus on the use of xanthates as collector agents. In the case of sulfide minerals, which are generally semiconductors, the interactions with xanthate collectors involve charge transfer across the electrical double layer at the solid-liquid interfaces. Woods *et al.* suggested three ways by which the xanthate ion could confer hydrophobicity to a mineral surface. Firstly the anodic reaction leads to dixanthogen formation (see eqn [1]). Secondly they distinguish between dixanthogen produced by the anodic reaction of the xanthate ion and the xanthate ion adsorption at a lower potential which is held by electrostatic attraction:

Finally there is chemisorption for which the anodic oxidation of the xanthate ion on lead sulfide is:

The corresponding cathodic reaction typically requires the reduction of oxygen in industrial flotation systems. If it assumed that the process is Faradaic in nature, i.e. no charge accumulation can occur, the oxidation and reduction reactions will be coupled by the flow of charge. The rate of the electrochemical reactions can now be determined by considering the driving force available for the process and the kinetics of the individual processes. If the respective electrical

and ionic resistance of the mineral and solution is low, the system will with time reach a common potential called the 'mixed potential' at which the individual reactions will take place at steady state. This will typically be the case for solutions with a high salt loading and with anodic and cathodic areas in close proximity. The situation may be further complicated by the involvement of more than two half cell reactions and also by cathodic and anodic areas of varying sizes as is typically the case in galvanic interactions.

The mixed potential theory has been used to account for the collectorless flotation of sulfide minerals such as chalcocopyrite, by considering the contributions of both surface oxidation and oxygen reduction reactions to the common potential. For example, Trahar has shown that surface oxidation of sulfide minerals results in the formation of hydrophobic sulfur layers and thus enhances flotation. It has been suggested that for sulfide minerals, surface oxidation involves the progressive removal of metal atoms, leaving a hydrophobic, metal-deficient sulfide layer with a crystal lattice only marginally altered from the original structure. More recent studies by Buckley and Woods, using X-ray photoelectron spectroscopy, have confirmed that sulfur species are indeed formed on the mineral surfaces. The concepts are summarized in Figure 1.

In the presence of xanthate collector conditions for the formation of dixanthogen have been shown by Allison *et al.* to occur when the rest potential of the mineral is greater than the reversible potential of the xanthate/dixanthogen couple E_R (0.13V at pH 7.0), which for these minerals is the active collector species in xanthate-based flotation, except for galena, where the metal xanthate was indicated, as discussed by Cheng and Iwasaki (see Further Reading). The rest

Chalcocopyrite	+ 0.14	0.115–0.355
Galena	+ 0.14	0.142–0.172
Molybdenite	+ 0.16	
Pyrrhotite	+ 0.21	0.055–0.290
Pyrite	+ 0.22	0.389–0.445
Arsenopyrite	+ 0.22	0.277–0.303

potential of a mineral surface, is the potential associated with a finite reaction rate in a specific solution environment (see Table 1). This is illustrated by Figure 2 from the work of Gardner and Woods, which

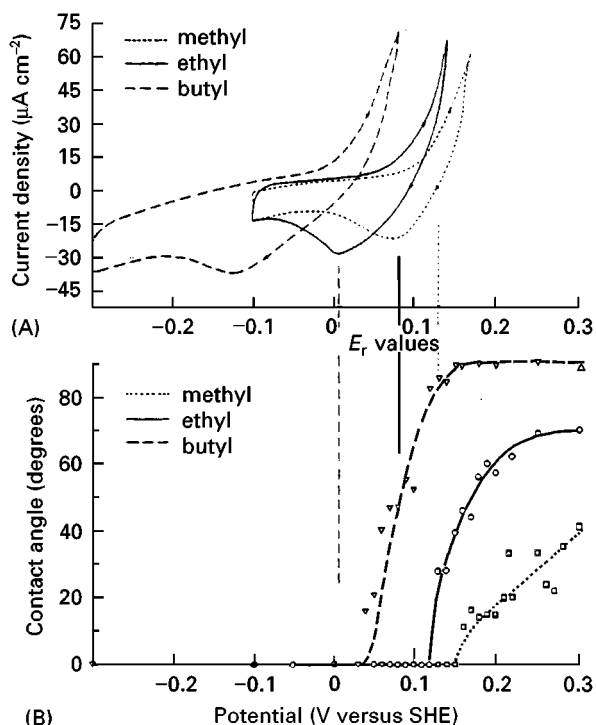

Figure 2 Pyrite electrode at 25°C in 0.05 M $Na_2B_4O_7$ solution (pH 9.2) containing 1000 ppm of three potassium alkylxanthates. (A) Cyclic voltammograms at $4 mV s^{-1}$; (B) Contact angles measured after holding the electrode at each potential for 30 s. The vertical lines are the E_r values for the xanthates. clearly indicates that of pyrite hydrophobicity only develops at potentials more noble than the reversible potential for xanthate/dixanthogen reaction. For galena the response shown in Figure 3 is somewhat different, with a significant current flow occurring below E_R due to the contribution of the chemisorbed reaction. It is also interesting to observe a zero contact angle at -0.2V .

Galvanic Interaction between Sulfide Minerals in a Pulp

As indicated earlier, galvanic interactions arise between two or more dissimilar minerals, and/or metals that are in electrical contact with each other and with an electrolyte. Electrochemical reactions at the min-

eral surfaces result in coupled current and ion flows. The cathodic reaction is generally the reduction of oxygen to hydroxide, while the oxidation reaction involves the oxidation of the sulfide mineral. The current flow depends on the surface area and conductivity of the mineral as well as the chemical composition of the electrolyte.

Minerals can only be separated by flotation if they are physically separate, i.e. liberated from each other. Short periods of galvanic contact between sulfide particles are unlikely to result in the development of the longer-term hydrophobicity that would be required for flotation. Polarization studies by Gardner and Woods on lead sulfides have indicated that the formation of hydrophobic substances, in this case lead xanthate, is reversible and thus unlikely to endure long enough for bubble contact to be established. In the context of the selective flotation of sulfides it would be the middlings, where the different sulfides would still be in physical contact, that would be the most influenced by galvanic interactions.

In the case of middlings it is possible that the floatability may even be better than that of pure minerals, due to the greater spatial separation and electric potential differentiation of the anodic and cathodic sites on such composite particles compared to single mineral particles. The possibility for spatial separation will increase with increasing conductivity of the solution and will be more important in solutions of high salinity.

As an indication of the galvanic interactions that may develop between different sulfides, a list of rest potential values has been reproduced in Table 1. The rest potential values mentioned were determined at near neutral pH values and will generally decrease with increasing pH. Because of this effect, many sulfides may be depressed by an increase in pulp pH, as their potentials move further away from the dixanthogen/xanthate equilibrium potential.

This disregards any chemical changes that may occur on the mineral surfaces due to a rise in alkalinity. High pH conditions typically develop at the cathodic sites, which favour the precipitation of metal hydroxides and would encroach on the anodic reaction site if the spatial separation of the sites is not large.

Consider the flotation of a middlings particle containing chalcopyrite and pyrite. In the absence of a xanthate collector, pyrite acts as a cathode of the local pyrite-chalcopyrite cell. Oxidation of the chalcopyrite surface is the predominant reaction balanced by the corresponding reduction reaction on the pyrite surface.

Buckley and Woods demonstrated that the collectorless floatability of chalcopyrite and pyrite

middlings particles increases with the amount of quartz added. This was attributed to the adsorption of hydrophilic iron hydroxides from the sulfide mineral surfaces on the quartz surface.

The uptake of xanthate ion strongly depends on the rest potential of the sulfide mineral. For sulfide minerals with rest potentials above +0.13V, xanthate ions are oxidized at the mineral surface to dioxanthogen, which imparts hydrophobicity to the mineral surface. For bornite and chalcocite, whose rest potential was below that of the xanthate/dioxanthogen reversible couple, metal xanthate was identified. For sphalerite and stibnite, the reaction products could not be positively identified. Rao, Moon and Leja also indicated that contact between various sulfides and iron will result in the depression of the potential to such an extent that the oxidation of xanthate to dioxanthogen will no longer be possible. This is indicated in Figure 4.

During electrochemical interaction between sulfide species, ionic charge transfer takes place through the flotation liquor, while electronic charge transfer takes place through the solid interface; solid phase conductivity, as well as water conductivity is thus important. As an example, it is the experience on the Phalaborwa igneous complex that plant water conductivities range generally between 180 mS (fresh industrial

water) and extremes of *ca.* 500 ms, with a middle range of 200–300 mS.

For separate mineral particles, the solid phase charge transfer would rely on particle collision, in which the gangue particles have a shielding influence. This reduces the galvanic interactions to a point where electrochemical interactions between fully liberated minerals are unimportant in flotation plant practice, unless plant waters are highly conductive, and both pulp densities and sulfide mineral concentrations are high enough.

Reaction Products Affecting Flotation Performance

General

The reaction products of galvanic interaction may influence the flotation efficiency of composite minerals by direct depression or activation of minerals, or by affecting flotation froth characteristics. These reaction products, as will be shown, are not unique to galvanic processes, but their rate of formation may be enhanced by such interactions. The spatial separation of the anodic and cathodic reactions in galvanic interactions favours the kinetics in the sense that the reaction products formed at the

Figure 4 Mixed potentials of sulfide minerals alone and in contact with metallic iron as a function of xanthate concentration. Nonoxidizing conditions, argon purging – 400 cc min⁻¹ natural pH, 25°C. (Reproduced with permission from Rao, Moon and Leja (1976) *Flotation*, A.M. Gaudin Memorial Vol. Copyright American Institute of Mining Metallurgical and Petroleum Engineers.)

anodic and cathodic sites do not directly interact to deposit potentially reaction stifling product on the anodic site.

The reaction products of galvanic interaction between mineral species can be distinguished on the basis of their location. Firstly, the reaction product may take the form of a surface modification of the mineral, e.g. a metal-deficient sulfide layer, supported and to a greater or lesser degree stabilized, by the underlying, unaltered phase. Secondly, the product may be chemically distinct from, and physically attached to, the original mineral particle. Examples of this are elemental sulfur and ferrous hydroxide coatings. Finally, the reaction product may detach and remove itself from the original mineral, like sulfate anions, copper cations, or ferric hydroxide particulates.

The anodic reaction of sulfides is presently thought to lead to the formation of metal-deficient, sulfur-rich surface species, by releasing an active metal ion which may form a metal hydroxide ($M(OH)_2$):

The formation of metal-deficient sulfide at the surface will tend to activate the surface and cause the metal hydroxy species to detach. However in the case of Fe^{2+} , species remain largely attached, leading to a blanketing effect that tends to hinder particle-bubble attachment. At suitable pH values, the release of reactive cations may lead to the unwanted activation of sulfide minerals, notoriously by copper ions.

As a general precaution against this reaction path, dissolved oxygen levels can be lowered. However, a lowering of pulp oxidative potential tends to lead to a general depression of flotation. An alternative is the elimination of metal-deficient sulfide species, or elemental sulfur, by reaction with aqueous sulfur dioxide:

This is a possible mechanism for galena depression with sulfur dioxide in flotation, in addition to other mechanisms postulated, i.e. a lowering of copper ion activity in solution, xanthate decomposition and a lowering of the oxidative potential below that necessary for xanthate oxidation to dioxanthogen.

A reaction path for the cathodic reaction of chalcopyrite, at neutral pH values and in oxygen-starved pulps, was also proposed by Li and Iwasaki:

Activating Species

The release of activating species may be accelerated by galvanic interaction. Activation of sulfide species, raising their floatability above that which is achievable naturally, can occur due to an enhancement of the hydrophobicity of the mineral, or due to the insertion or attachment of ions which are more reactive towards collector reagents than the host species. In the latter case, the main, but not only, ion to consider is copper, which may attach itself to a particle as follows, by direct replacement:

The reaction path can be favoured by the presence of a suitable cathodic particulate mineral, like pyrite, reacting along the lines of the following equation:

The effect of galvanic coupling in a conducting particle will cause an electron flow, which will facilitate the simultaneous cathodic reduction of the MS surface by reaction with $Cu(OH)_2$, and the anodic oxidation of MS both reactions producing hydrophobic surface coverings of Cu_2S and S^0 , respectively.

Another example is the activation of pyrite by lead ions. In support of the assertion that true electrochemical interaction is limited to composite particles, Zhang *et al.* found, importantly, that interaction between composite particles containing pyrite and sphalerite was negligible in the absence of metal ions in solution. In their presence, sphalerite was found to successfully compete with pyrite for the activating ions, and through their action to compete more successfully for xanthate, thus depressing the floatability of pyrite. Competition for activating species thus seems to be an important factor in the interaction between minerals in flotation.

Depressing Species

The formation of hydrated, oxidized surface species like iron hydroxide and basic sulfates, increases particle hydrophilicity, and will thus depress flotation. High thiosulfate levels, which may arise when milling under relatively nonreducing conditions, e.g. fully autogenous grinding, or laboratory grinding in porcelain mills, may lead to the precipitation of insoluble thio-salts, which may also depress flotation. The generation of soluble sulfide species, especially notable in stagnant, anaerobic water reservoirs with bacterial action, may lead to mineral depression, since the

sulfide and xanthate ions compete for the same surface sites.

Froth Characteristics Affecting Species

The effect of froth structure on flotation is usually related to its stability. Stable froths have small bubbles and a high entrained water content. The solids in the entrained water are approximately at their concentrations in the pulp; consequently their overflowing concentrates will be of low grade. The presence or absence of fine, colloidal particles has a profound effect on flotation froth structure and drainage, and thus overall flotation performance. The most notable example of this is the deleterious effect that copious quantities of (naturally floatable) talc particles have on sulfide flotation, with adverse results in grade, recovery, and rates of recovery. The same froth modifying effects can be noticed when dealing with colloidal precipitates. In practice, the noticeable effects are largely limited to iron hydroxides, due to their abundance in natural systems. Thus, a change in froth structure may be noted when hydrated ferrous hydroxide particles are oxidized to (less hydrated) ferric oxide. The latter species allows a more desirable, less slimy, froth structure. As another example, it has been strongly suggested that the common practice of copper sulfate addition in flotation plants, apart from activating effects, also has strong froth structure modifying effects.

Application to Plant Practice

Collectorless Flotation

For collectorless flotation, the formation of a metal-deficient sulfide layer on the particle surface must generally be targeted. Formation of such a layer may be accelerated and spatially accentuated by galvanic interaction. When considering the flotation of sulfide minerals in the absence of collector reagents, in the context of electrochemical mineral interaction, three factors can induce floatability. First of all, floatability can be natural, i.e. due to the crystal structure and chemical bonding of a mineral. Examples of such minerals are molybdenite, stibnite, and the arsenic sulfides realgar and orpiment. Secondly, collectorless flotation can be self-induced, i.e. under the right pulp oxidative potentials, surface products will form which induce hydrophobicity. Examples of this are pyrrhotite and chalcopyrite. Rao and Finch found that pyrite/sphalerite selectivity could be enhanced by first recovering the pyrite which is naturally floatable, due to a chemically formed sulfur layer, in the absence of a collector. A third cause of floatability is mineral size. As minerals decrease in size, their

recovery into flotation froths increases due to entrainment, rather than selective attachment to froth bubbles. A good example of this is galena flotation from complex ores. At one mine site, carrying out sequential copper–lead–zinc flotation, about three-quarters of lead recovery into the copper concentrate was found to be made up of galena particles smaller than 10 μm . Since this effect is physical rather than chemical, it can only be significantly affected by a change in physical parameters, e.g. froth lamellae thickness and particle size.

In the collectorless flotation of pyrite–chalcopyrite–quartz mixtures, Johnson found a dependence of flotation behaviour on the pyrite/chalcopyrite surface area ratio, which would be consistent with electrochemical interaction. In this work it was however shown as well that copper solubilization was not enhanced in the presence of pyrite, but rather reduced; this points to copper deposition on pyrite – in other words, to activation rather than direct electrochemical interaction. Interestingly, interaction was reduced in the presence of quartz, due to adsorption of metal ions onto the quartz surfaces. In this respect, adsorption studies on other gangue minerals showed that such scavenging of potentially activating ions from solution may be substantial.

Pulp Oxidative Potential Control

Hayes and Ralston showed that the control of pulp oxidative potentials allows flotation selectivity, and is therefore a worthwhile approach in the flotation of complex sulfide ores, in addition to pH strategies. Direct electrochemical interactions between physically separated sulfide minerals, in which one affects the other's flotation behaviour directly through an anode–cathode relationship, have so far not been convincingly demonstrated on plant scale.

Galvanic and electrochemical interaction between sulfide minerals, and general chemical reactivity, is to a large degree dependent on the presence of oxygen in solution. The control of oxygen levels is thus generally the objective and result of pulp oxidative potential control. Since industrial flotation relies heavily on the use of ambient air, it has been proposed to regulate the oxygen concentrations entering flotation by admixture of nitrogen, or by partial re-circulation of process air released from the froth surface. The former approach is expensive whereas the latter depends on cells specifically designed to collect and re-circulate air leaving the top surface of the froth. Cylindrical cells seem to be most effective in this respect. The gas composition of bubbles generated by pressure differentials in flotation cells is dependent on a suite of factors, including the magnitude of

the pressure drop, dissolved substances, and nature of the nucleating surfaces. Benefits in flotation results were shown when regulating certain reagent additions on the basis of pulp oxidative potential, e.g. sulfuric acid, rather than pH. However, benefits might well be mostly due to froth structure improvements.

Trahar has shown that interactions between sulfide minerals were much decreased if they are ground separately, and only combined in the flotation cell. In this case, no mineral interaction between chalcopyrite, galena and sphalerite could be statistically proven. This demonstrates that galvanic interaction between sulfide minerals is only practically noticeable when mechanical contact exists. Grano *et al.* have also found that flotation selectivity between sulfide minerals is most sensitive to milling and preconditioning parameters, more so than to oxidative potentials during flotation itself, and mostly due to the presence of mild steel particles originating from equipment wear. For this reason, amongst others, research into comminution techniques which maximize mineral separation, whilst minimizing smearing, overgrinding, and steel consumption, must be a priority in the minerals industry. The effect of mild steel particles generated during ore comminution is mainly due to oxygen consumption, corrosion inhibitors being essentially ineffective. Full oxidation of these particles during conditioning removes their deleterious effect. Even for real ores containing significant quantities of more than one sulfide mineral, reasonable correlations exist between the behaviour of minerals in the ore and single minerals, as found by Grano *et al.* This indicates the limited extent of electrochemical mineral interactions in general practice.

Conclusion

True electrochemical interactions between sulfide minerals on industrial size plants are thought not to be of practical significance, except when physical contact between dissimilar sulfides exists (middlings), and/or at high pulp densities, high sulfide concentrations in the flotation feed, and high water conductivities. More importantly, sulfide minerals are found to interact through competitive adsorption of activating ions, the reduction of oxygen levels in the flotation pulp, and froth modifying activity of mineral oxidation products. Middlings particles, composed of two or more sulfides, do however experience electrochemical interaction, the result of which appears to be an enhancement of floatability, leading to a reduction in concentrate grades. The solution to such a problem is however more to be sought in comminution technology than electrochemical intercession.

Oxidative potential control offers advantages in industrial flotation separations, but its effect does not appear to be an interference with electrochemical mineral interactions.

Introduction

The froth flotation process is commonly employed for the selective separation of a mineral species from a liquid–solid suspension of both valuable and unwanted gangue mineral particles. The valuable mineral species (which needs to be separated) is rendered hydrophobic by controlling its surface chemistry to provide the potential conditions for the attachment of the particles to air bubbles. The bubbles and particles are made to interact with each other inside a flotation machine. The flotation machine, depending on its operating conditions, provides an environment for the bubble–particle attachment and permits levitation of bubble–particle aggregates to the froth. The manner in which bubbles and particles interact with each other depends on the cell operating conditions and the type of flotation machine used.

Flotation machines, in general, may be categorized into four different classes: (i) mechanical or conventional cells; (ii) energy-intensive pneumatic cells; (iii) column cells; and (iv) froth separators. Of these, mechanical flotation cells have dominated the mineral industry since the early days of flotation and account for a significant amount of minerals processed. The aim of this article is to describe the operation and design of mechanical flotation cells.

Cell Operation

A mechanical flotation cell essentially consists of a vessel or a tank fitted with an impeller or rotor. The impeller agitates the slurry to keep particles in suspension, disperses air into fine bubbles and provides an environment in the cell tank for interaction of bubbles and hydrophobic particles and their subsequent attachment and therefore separation of valuable mineral particles from the undesired gangue mineral particles. The bubble–particle aggregates move up in the cell by buoyancy and are removed from the cell lip into an inclined drainage box called a launder (Figure 1). The launder product is commonly known as concentrate. The particles that do not attach to the bubbles are discharged out from the

bottom of the cell tank to the discharge or tailings box (Figure 1).

Hydrodynamic Zones

A mechanical flotation cell necessitates generation of three distinct hydrodynamic zones for effective flotation. The region close to the impeller encompasses the turbulent region necessary for solids suspension, dispersion of gas into bubbles and bubble–particle interaction for collection of minerals on the surface of the bubbles. Above the turbulent region lies the quiescent zone where the

Figure 2 Hydrodynamic zones in a mechanical flotation cell.

bubble-particle aggregates rise up in a relatively less turbulent region. This region also helps in reducing the number of gangue minerals which may have been entrained mechanically or entrapped between bubbles for upgrading of valuable minerals. The region above the quiescent zone is the froth zone that serves as an additional cleaning step and improves the grade of the concentrate product. The three hydrodynamic zones in mechanical flotation cells are depicted in Figure 2.

The conflicting functional requirements in different zones in a mechanical flotation cell are a challenge in terms of the cell design and a fine balance of hydrodynamic conditions is necessary for the optimum recovery of valuable minerals in a cell.

Gas Dispersion

One of the most important hydrodynamic conditions in a mechanical flotation cell is dispersion of gas into fine bubbles. The bubble generation mechanism in

a mechanical cell is a two-stage process. Firstly, air cavities are formed at the trailing edge of the impeller blades, which is the low pressure region. Thereafter, bubbles form by shedding of vortices from the tail of the cavity, as shown in Figure 3.

The dispersion of air into bubbles can be characterized by three properties: bubble size, gas hold-up and superficial gas velocity. Mean bubble size in industrial mechanical cells varies, in general, from 0.5 to 2 mm; gas hold-up varies from 5 to 15% and superficial gas velocity varies from 0.6 to 1.5 cm s⁻¹, depending on cell operating conditions (impeller speeds and air rates) and the cell duty in plant operation – roughers, scavenging, cleaners, etc. Recent studies have shown that bubble size, gas hold-up and superficial gas velocity cannot describe the gas dispersion in a mechanical cell adequately when taken individually; but when taken together the gas dispersion properties determine the bubble surface area flux S_b in the cell, which has been shown to characterize gas dispersion very well. Typical S_b values in industrial cells vary from 30 to 60 s⁻¹. The concept of S_b has been found to be useful in metallurgical scale-up and cell optimization, design and selection.

Mode of Air Entry

In mechanical cells there are two modes by which air is introduced into the cells; one is the forced air entry mode carried out using a blower and the other is the self-induced air entry mode, in which air is sucked into the cell by vortexing. The two cell designs can be distinguished by the difference in vertical location of the impeller in the cell. In the forced air-type machine, the impeller is located close to the cell bottom with a deeper impeller submergence, and an external air blower is used to supply air under pres-

Figure 3 Schematic diagram of formation of bubbles in mechanical cells (after Grainger Allen, 1970; courtesy of Transactions of the Institute of Metallurgy, UK).

sure through the hollow shaft to the impeller region. Self-induced air machines utilize a standpipe which shrouds the drive shaft which is solid. The impeller is located almost in the midpoint of the cell which draws air through the space between the standpipe and the solid shaft.

Flow Patterns

The impeller in a mechanical flotation cell, during rotation, generates a vortex at the bottom of its blades drawing slurry from its lower section and discharging out from its upper section of the blades. Air is introduced through the impeller shaft or in the spacing between the shaft and a standpipe depending on whether the cell is forced air type or self-induced type, as described above. The dispersed air bubbles come in contact with the slurry close to the impeller discharge point. The aerated slurry flow then leaves the impeller mechanism for the surrounding tank volume. The impeller, therefore, acts as a pump drawing in slurry from below and expelling the aerated slurry to the cell volume. A typical flow pattern of a mechanical cell is shown in Figure 4.

Cell Design

The essential components of a mechanical flotation cell are described below.

Cell Tank

The profile of a cell tank is rectangular with truncated corners, U-shaped, conical or cylindrical, depending on cell type and size. Typically, mechanical cells are designed with a rectangular tank bottom for cells with volume up to 3 m³ and a U-shaped bottom for cells with volume up to about 38–45 m³. Cells larger than 38–45 m³ are typically cylindrical with either a conical or a flat bottom. Figure 5 shows a schematic of different tank designs.

In a typical plant, the mechanical cell tanks are arranged in a series called a bank. The number of cells in a bank varies depending on cell size, application and plant circuit configuration. The tailings from the first cell move on as the feed to the second cell and so on and the tailings from the last cell form the final tailings of the bank. The concentrates from different cells are combined in different ways depending on the requirements of the circuit. For example, in a cleaner bank, the concentrates from the first two cells may be combined to form the final concentrate products, whereas the concentrate product from the rest of the cells may be combined and recirculated to the feed of the cleaner bank.

Feed Box and Discharge Box

Each bank in a flotation circuit (which could also be an individual cell) is usually fitted with a feed box

Figure 4 Typical flow patterns in a mechanical flotation cell (courtesy of Outokumpu Mintec Oy, Finland).

Figure 5 Typical tank designs in mechanical flotation cells.

with a rectangular opening at the bottom of the box to allow entry of slurry into the cell bank for flotation. The feed box is rectangular or half-cylindrical in shape depending on cell type and size. A tailings box or discharge box is also fitted at the end of the bank (or on the opposite side of feed box in an individual cell) to allow discharge of tailings. The discharge box is also rectangular or half-cylindrical in shape. **Figure 6** shows a typical arrangement of a feed and a discharge box in mechanical flotation cells. For some cell types and sizes, a dart valve or overflow weir are fitted in the discharge box to control pulp level in the cell tank. For other designs, a discharge box is not used and a pinch valve is fitted to the tailings outlet pipeline instead for pulp level control.

Cell Launderers

Launderers in flotation cells are located outside the overflow lip to collect and transport the froth or concentrate product out of the cell tank. Launderers are typically located on the top of the cell tank, as shown in **Figure 1**. Launderers are designed with a slope of about 10–15° for smooth transportation of froth without blockage in the launderers.

The design of launderers varies with cell size and type. The launderers are located on opposite sides adjacent to the feed and discharge boxes in rectangular cell tank designs, as shown in **Figure 1**. Launderers on three sides are also common in rectangular cells ar-

ranged in series. Large cylindrical cells have concentric launderers which can be either internal or external or both, depending on the capacity of launder necessary for froth removal.

Impellers or Rotors

The impeller or agitator, also referred to as the rotor, is considered to be the heart of a mechanical flotation cell as it provides the energy to perform the following functions necessary for the flotation process:

1. Suspension of solids in the cell tank.
2. Dispersion of air into bubbles.
3. Creation of microturbulence for effective bubble-particle collision.
4. Suction of air into the cell in self-induced type cells.

The design of an impeller varies with cell type. Most impeller designs have a flat circular disc with different shapes of blades or fingers fitted to the disc concentrically to the lower section of the disc. The shape of the blades or fingers varies from cylindrical to tapered (half-spherical). The half-spherical impeller design is more popular in the new design of cells and details of this design will be discussed later in this article. The top section of the disc connects to a drive shaft which in turn connects to the pulley/gear-motor drive assembly. The impeller is located in the centre of the cell cross-section with its

submergence varying with cell type and mode of air entry. **Figure 7** shows the shapes of different commercially available impellers.

Stators or Diffusers

A stator or diffuser is an important component of a mechanical flotation cell, which surrounds the impeller and acts as an internal baffle useful in reducing pulp vortex in the cell. The tangential flow of the agitated slurry (due to rotation of the impeller) is transformed to a radial direction for effective dispersion of gas and solids in the cell tank. This reduction in the vortex flow helps in maintaining a stable pulp–froth interface, essential for flotation.

A stator consists of a number of blades arranged in a concentric circle with gaps between the blades to facilitate movement of slurry in the cell tank. A stator is usually mounted on the bottom of the cell tank surrounding the impeller concentrically from its bottom. In some cell designs the stator is fitted to the standpipe such that the stator shrouds the impeller from the top and hangs with an open space at the bottom: this is commonly known as an overhung stator.

The impellers and diffusers are moulded and coated with rubber or polyurethane for abrasion resistance.

Impeller Drive Assembly

The impeller connected to the shaft (hollow or solid) is driven by a three-phase induction motor with the help of V-belts, pulleys or gear box. A typical drive arrangement in a mechanical cell is shown in **Figure 1**. The size of the drive and the motor pulleys determine the speed at which an impeller operates.

Cell Types and their Designs

Most of the industrial mechanical flotation cells in the early days (before the 1970s) were of the cell-to-cell type (tanks of different cells connected in a row) for small plants and multistage cleaner floats where the pumping action of the impellers permitted the transfer of intermediate flows without external pumps. With the emergence of large flotation cells, since the early 1980s, dictated by economic considerations, open flow cells (with slurry flowing openly through a series of cells in a bank) have become prominent.

In the 1980s many mechanical cell designs were prevalent around the world. The major ones are:

1. Agitair cells from Galigher company, USA.
2. Aker machines from Aker Trondelag, Norway.
3. BCS cells from Minemet Industrie, France.
4. Booth cells from Booth Company, USA.
5. Denver cells from Denver Equipment Limited, Joy Industrial Company, USA.

6. Krupp cells from Krupp Polysius AG, West Germany.
7. Maxwell cells from Technequip Ltd, Canada.
8. Mechanobre cells from Machineoexpert V/O, USSR.
9. OK cells from Outokumpu Oy, Finland.
10. Sala cells from Sala International AB, Sweden.
11. Wedag cells from KHD Humboldt Wedag from West Germany.
12. Wemco cells, Wemco division, Envirotech, USA.

Only a handful of these cell manufacturers have survived the competitive global market by improving their products or by mergers or by diversification. Manufacturers of Wemco and Outokumpu cells, through research and development, have consistently updated their technology to remain competitive. The recent Tankcells (designated as OK-TC) and Smart-cells from the manufacturers of Outokumpu and Wemco cells, respectively, are an example. Some new designs, such as the Bateman BQ and Svedala RCS cells, have emerged in the mid 1990s. The companies which manufactured Denver and Sala cells have been procured by Svedala and their cells are marketed by Svedala's Pumps and Process division. The Agitair cells are now marketed by Baker Process (previously known as EIMCO Process Equipment Company). KHD Humboldt Wedag have stopped manufacturing mechanical cells and now market a newly developed pneumatic cell known as Pneufloat.

Presently there are five major manufacturers of mechanical flotation cells. Details of the design features of different cells are described in the sections below.

Bateman Cell

The Bateman flotation mechanism was developed in 1993 and is presently marketed by the Bateman Process Equipment Limited. The BQR series of Bateman cells have a round tank design with cell sizes varying

Table 1 Bateman cell tank dimensions for different cell sizes (courtesy of Bateman Process Equipment, South Africa)

Model	Volume (m ³)	Height (m)	Depth (m)	Installed motor (kW)
BQR 50	5	2	2	NA
BQR 100	10	2.5	2.5	45
BQR 200	20	3.2	3	55

BQR 500	55	4.2	4.34	115
BQR 750	75	5.2	4.5	132
BQR 1000	100	5.5	4.95	132

Figure 8 A schematic diagram of the Bateman flotation cell (courtesy of Bateman Process Equipment, South Africa).

from 5 m³ (BQR 50) to 100 m³ (BQR 1000). The tank dimensions of different cells of varying sizes are given in Table 1. The unit cell design Bateman cells are called HiFlo™ and HiClean™ machines.

The Bateman mechanism consists of a hemispherical-shaped impeller which is connected to a solid drive shaft. The impeller is designed with no disc on the top and the impeller blades have both the top and bottom opened. The drive shaft is shrouded with a stand pipe. The Bateman mechanism utilizes the forced air entry mode and air is supplied into the mechanism through the gap between the standpipe and the shaft. The mechanism utilizes an overhung-type stator (or diffuser) connected to the bottom of the standpipe, which is a horizontal hood with baffle plates projecting downwards (Figure 8).

Dorr-Oliver Cells

The Door-Oliver cell is marketed by Dorr-Oliver, a global corporation and member of the Krauss-Maffei Group.

The Dorr-Oliver Company Limited manufacturers flotation cells in a wide range of sizes. Cells with a volume of 0.03 m³ (DO 1) to 2.8 m³ (DO-100) have a flat-bottom tank design. Cells with volumes from 4.2 to 44 m³ come with a U-shaped tank bottom. Cells with volumes from 50 to 150 m³ are available with a round tank with a conical bottom. Details of tank dimensions for the Dorr-Oliver cells are given in Table 2.

Table 2 Dorr-Oliver cell tank dimensions for different cell sizes (taken from Dorr-Oliver flotation cell brochure; courtesy of Dorr-Oliver, Australia)

The Dorr-Oliver mechanism consists of a hemispherical-shaped impeller fitted to a hollow shaft. The mechanism utilizes the forced air entry mode in which air is introduced to the impeller through the hollow

shaft. The stators for the Dorr-Oliver cells are generally mounted on the bottom but the large cells mechanisms are designed with an overhung stator.

Figure 9 shows a schematic diagram of a large Dorr-Oliver cell with a tank design.

**Figure 9** Schematic diagram of a large Dorr-Oliver cell (courtesy of Dorr-Oliver, Sydney, Australia).

Outokumpu Cells

Outokumpu Mintec, a Finnish company which belongs to the Outokumpu Group, operates internationally and has been the manufacturer of the Outokumpu flotation cell for the last 30 years.

Outokumpu produces different flotation machines which can be categorized as:

1. OK conventional flotation machines: for rougher, scavenger and cleaner flotation.
2. OK-TC (TankCell) flotation machines: for rougher and scavenger flotation.
3. SK flotation machines: for Skim-Air Flash flotation in the grinding circuit.
4. HG flotation machines: for cleaner flotation.

The OK conventional flotation cells are available in volumes up to 38 m³. Conventional cells have a rectangular tank design for cell volumes up to 3 m³; above 3 m³ and up to 38 m³ the cells have a U-shaped tank. TankCell designs are available from a volume of 5 m³ to a volume of 160 m³ and are essentially a cylindrical

Figure 10 A schematic diagram of Outokumpu TankCell (courtesy of Outokumpu Mintec Oy, Finland).

cell with a flat bottom (Figure 10). The tank dimensions of different cells are given in Table 3.

The OK impeller mechanism is designed with a hemispherical-shaped impeller consisting of a

horizontal disc on the top which is attached to a number of narrow vertical slots tapered downwards. The impeller has separate slots for air and slurry movement. The mechanism has a forced air type entry mode in which air is brought into the impeller through a hollow shaft.

The stator in the OK mechanism is mounted on the bottom of the tank. There are two stator designs used in an Outokumpu cell: one is known as the multi-mix or conventional stator and the other is known as free-flow. The multi-mix stator is typically used for fine particle flotation, whereas the free flow stator is typically used for coarse particle flotation.

Svedala Cells

The former manufacturers of Denver flotation cells (Denver Equipment, USA) and Sala cells (Sala International in Sweden) have merged together to form the Svedala Pumps and Process Division, which is part of the worldwide Svedala Industri group. Both Denver and Sala cells are available through Svedala companies located worldwide.

The Svedala flotation cells include mechanical flotation cells in the AS range (previously known as Sala cells), in sizes from 0.03 to 16 m³; the DR range

(previously known as Denver cells), in sizes from 0.09 to 42.5 m³; and cell-to cell machines in sizes from 0.08 to 14.2 m³.

In 1995 Svedala developed a new design of flotation cell known as the RCS Flotation machine which comes in sizes from 5 to 200 m³. The tank dimensions of different cells sizes are shown in Table 4.

The RCS Flotation machine utilizes a new DV (deep vane) mechanism. The DV mechanism consists of vertical rectangular blades or vanes tapered at the

bottom. The blades are connected to a circular horizontal disc located just above the centre of the blades. The mechanism is designed with an overhung stator with vertical vanes projecting downwards connected to the mechanism standpipe. Depending on cell application, the DV mechanism can be modified in two different ways to suit the application. The design of the mechanism which allows entry of air through a hollow drive shaft is known as the DVH mechanism (deep vane and hollow shaft), whereas the design which allows entry of air through a concentric standpipe is known as the DVS mechanism (deep vane and solid shaft).

Figure 11 shows a schematic of the Svedala RCS flotation cell, showing the DV mechanism and the cell tank design.

Wemco Cells

Wemco flotation cells are manufactured by Baker Process, which also makes Agitair cells and pyramid column cells.

There are two major Wemco designs, the Wemco 1 + 1 design and new SmartCell design (Figure 12). The 1 + 1 design comes in cell sizes from 0.57 to 85 m³. The SmartCell design comes in sizes from 8.5 to 160 m³. The Wemco 1 + 1 cell utilizes the self-induced air entry mode and consists of a rotor,

dispenser, standpipe and a hood. The larger cells are designed with a false bottom and draught tube. The SmartCell flotation machine utilizes the Wemco 1 + 1 aeration mechanism which is reconfigured and embedded with an expert control system. The dimensions of different Wemco cells are shown in Table 5.

The air and pulp circulation in the Wemco cells are determined by the rotor size, speed and submergence in the pulp. Liquid circulation and air transfer are a function of rotor speed, size and submergence.

Present and Future Trends

Traditionally, flotation machine design closely follows the trend of comminution machines in mineral-processing plants. Due to economic considerations in

the processing of low grade ores, the present comminution machines such as crushers, semi-autogenous, autogenous and ball mills are designed for very high capacities. The Cadia Hill Mine in New South Wales, Australia, which treats a copper-gold ore at the rate of 2100 tonnes per hour, utilizes a 12 m diameter SAG mill (with a 20 MW motor) and two 6.5 × 11 m ball mills (each with a 8.75 MW motor). To be compatible with the comminution circuit, large capacity 150 m³ flotation cells are used in the rougher circuit.

At present, cells as large as 300 m³ are being designed by various manufacturers. Installation of large cells has many advantages:

1. reduction in capital costs;
2. reduced size of plants;
3. reduced power consumption;
4. reduced maintenance;

5. easy control;
6. reduced reagent consumption.

However, with increase in cell size, the problem of machine design and metallurgical scale-up becomes more acute. The scale-up features that may have been tolerated on smaller cells are not applicable to larger cells. The simple similitude considerations used in terms of dimensionless numbers (power number, Froude number, air flow number, Reynolds number) are not sufficient to design large machines. The development and evaluation costs rapidly increase with cell size, which calls for a more rational and fundamental basis in cell design. Extensive research at the Julius Kruttschnitt Mineral Research Centre in Brisbane has shown that bubble surface area flux or S_b is an important criterion for metallurgical scale-up, which will gain more prominence in the future and will be considered as a parameter in conjunction with other important dimensionless numbers used in machine design and scale-up.

An increase in cell sizes also requires more effective froth transportation due to the increase in travel time of bubble-particle aggregates which results in high drop-back and low froth recovery. To address the problem of froth transportation and stability in large cells, new design features such as internal launders, double launders, high capacity launders, booster cones, froth crowders, cross-launders and beehive launders are emerging. More work will be carried out by cell manufacturers and researchers to understand froth transportation and froth recovery. The effect of the interactions of different launder designs, froth crowders and cell-operating parameters such as impeller speed, air rate and froth depth will be the subject of further investigation for better cell design and optimization of cell operation.

The design differences of various cells marketed by different manufacturers are in fact differences in impeller/stator mechanisms and air input systems (either self-induced or forced air type through a standpipe with a solid shaft or through a hollow shaft). However, the design of tanks is similar for different cell types, and resembles the cylindrical design of the old Maxwell cells. The launder and froth crowding devices in different designs are tailor-made to suit different applications.

The large new flotation cells are equipped with integrated control systems. The recent trend of installation of a few large cells in a circuit will see more control instrumentation like air flow control, variable speed drive for speed control, as well as online

measurement equipment for monitoring bubble size, superficial gas velocity, gas hold-up and bubble surface area flux, which will be used for better cell performance optimization. Froth vision equipment will also gain prominence for better control of froth in the large flotation cells.

The development of flotation cells will continue as more and more fine particle processing will be necessary in future. The large flotation machines will have to be designed to generate very small bubbles and a high degree of microturbulence for effective bubble-particle collision to remain competitive against other novel technologies like high intensity pneumatic cells. Entrainment will be a major issue in concentrators, which will need refinement of froth-washing technologies in mechanical flotation cells.

Acknowledgements

The authors would like to thank the manufacturers of Bateman, Dorr-Oliver, Outokumpu, Svedala and Wemco cells for providing sale catalogues, pictures and other information regarding their flotation cells.

Foam Fractionation

G. Narsimhan, Purdue University,
West Lafayette, IN, USA

Copyright © 2000 Academic Press

Introduction

Foam concentration/fractionation is a separation technique in which surface-active solutes are either concentrated from a dilute solution or separated from a mixture by preferential adsorption at a gas-liquid interface created by sparging an inert gas through the solution. These gas bubbles entrain the surfactant solution and form a stable foam with a large gas-liquid interfacial area. As the foam moves through the column, the surfactant solution tends to drain due to gravity and capillary forces. This results in a decrease in the amount of liquid in the foam. The reduction in the entrained liquid is first associated with the bubbles forming the closest spherical packing, after which they will deform to a dodecahedral shape and then possibly coalesce. Consequently, there is an increase in the gas-liquid interfacial area per unit volume of the liquid. The surfactant tends to adsorb preferentially at the gas-liquid interface. At the top of the column, the foam is sent to a foam breaker where the foam is broken either mechanically or chemically. This results in either enrichment or concentration of more surface-active protein because of the recovery of adsorbed protein from the gas-liquid interface into the bulk entrained liquid. In the case of a dilute solution of a single protein,

the extent of enrichment would depend upon the relative amount of adsorbed protein compared to that in the bulk entrained liquid. In the case of a mixture of proteins in solution, the separation of a protein from the mixture would depend upon the extent of preferential adsorption of that protein at the gas-liquid interface. Since the adsorption isotherm usually leads to a much higher proportion of adsorbed protein at very low bulk concentrations, foam concentration is very effective for extremely dilute solutions.

Because of the presence of hydrophilic and hydrophobic functional groups, proteins are surface active. Therefore, foam-based separations are viable for concentration/separation of protein solutions. Foam-based separation has been applied to various proteins and enzymes. Experimental investigation has been summarized in Table 1. This review highlights the theoretical aspects of prediction of enrichment and separation of proteins and enzymes in a foam fractionation column.

Different Modes of Operation of a Foam Column

Figure 1 depicts the different modes of operation of a foam fractionation column. The simplest mode is the production of a protein-rich concentrate phase from a dilute aqueous protein solution. This can be operated as semi-batch mode (Figure 1A), in which a pool of protein solution is maintained at the bottom

Figure 1 Different modes of operation of a foam fractionation column.

of a column and is sparged with an inert gas which forms the foam. The foam is continuously removed at the top of the column, sent to a foam breaker and the top product collected. Since the most surface-active protein is preferentially removed from the solution, the solution would progressively get depleted in that protein as time progresses. As a result, the pool would get enriched in other components in the case of mixtures. In continuous operation, a feed stream of protein solution is introduced into the pool and the bottom product withdrawn (Figure 1B). Sparging of gas bubbles mixes the liquid pool well enough so that the bottom product is at the same composition as the liquid pool. In addition, the continuous foam column can also be operated in stripping, enriching or combined modes. In the stripping mode, the object is to remove, almost completely, protein from a dilute solution. In this mode, the feed is introduced into the foam and trickles down countercurrently through the rising foam (Figure 1C). The protein concentration in the liquid below the feed-point falls with foam depth, due to it being adsorbed on to the rising bubble surface. There is a net upflow of solution through the foam maintained by entrained up-flowing liquid from the pool. If the foam column is deep enough the protein adsorbed on the bubble surface Γ_B will be in equilibrium with the feed liquid concentration c_F and the pool liquid concentration will be very low. Consequently, the bottom product is stripped of more protein than that in the simple mode of operation. In the

enriching mode (Figure 1D), the feed stream is introduced into the liquid pool and part of the top product that is obtained by collapsing the foam is refluxed into the column. Protein-rich reflux flows down countercurrently through the foam resulting in further enrichment of protein in the top product. In the combined mode (Figure 1E), the feed is introduced into the foam and the external reflux is used. Part of the column above the feed acts as an enricher, whereas the bottom part of the column acts as a stripper.

It is reasonable to assume that the residence time of the bubbles through the liquid pool is sufficiently large for protein adsorption to reach close to equilibrium so that the surface concentration of protein at the gas-liquid interface can be assumed to be close to the equilibrium value. Also, if bubble coalescence in the foam bed is negligible, the concentration of protein in the interstitial liquid can be expected to be the same as that in the liquid pool. For simple mode of operation of the foam column with a continuous feed stream consisting of a dilute protein solution, the top product concentration c_D , is related to the pool concentration c_B via:

$$c_D = c_B + \frac{6G\Gamma_B}{dD} \quad [1]$$

where G is the gas flow rate, D is the top product flow rate, d is the bubble size and Γ_B is the equilibrium surface concentration of protein at the gas-liquid interface corresponding to the pool concentration. In the above equation, the first term on the right-hand side is the contribution to the protein concentration from the bulk interstitial liquid before the foam is collapsed and the second term is the contribution from the adsorbed protein at the gas-liquid interface which is recovered into the bulk upon collapse of the foam. A mass balance around the column now gives the following equations for the top product concentration c_D and the bottom product concentration c_B respectively (Lemlich, 1968):

$$c_D = c_F + \frac{6G\Gamma_B}{d} \frac{B}{F(F-B)} \quad [2]$$

and:

$$c_B = c_F - \frac{6G\Gamma_B}{Fd} \quad [3]$$

where c_F is the feed concentration, c_B is the pool concentration, F is the feed flow rate, and B is the bottoms flow rate. In the case of binary mixture of

two proteins, the separation efficiency S , defined as the ratio of the two enrichments, is given by:

$$S = \frac{c_{D,2} c_{F,1}}{c_{F,2} c_{D,1}} = \frac{1 + \frac{6G\Gamma_2(c_{B,2})}{dc_{F,2}} \frac{B}{F(F-B)}}{1 + \frac{6G\Gamma_1(c_{B,1})}{dc_{F,1}} \frac{B}{F(F-B)}} \quad [4]$$

where the subscripts 1 and 2 refer to components 1 and 2 and $\Gamma_i (c_{B,i})$ is the equilibrium surface concentration of component i corresponding to the bulk concentration $c_{B,i}$. It can easily be seen that the separation ratio is greater than unity if component 2 is more surface active than 1. Also, in the above equation factor 6 arises because the area per unit volume of spherical bubbles of diameter d is $6/d$. If the dodecahedral shape of the bubbles in the foam is to be accounted for, factor 6 is to be replaced with 6.59. For a Langmuir adsorption isotherm, the surface concentration of proteins is related to the bulk concentration via:

$$\Gamma_i = \frac{K_i c_i}{1 + \sum_i K_i a_i c_i}, \quad i = 1, 2 \quad [5]$$

where K_i is the equilibrium constant, c_i is the bulk concentration and a_i is the area occupied by a protein molecule.

In the stripping mode, the feed stream is introduced into the foam (Figure 1C). For a long stripping column, the protein concentration of downflowing interstitial liquid will approach that of entrained liquid in the foam. The two concentrations will approach each other at the feed level. Therefore, the protein concentration of the interstitial liquid at the top can be taken to be the feed concentration. Therefore, mass balance around the foam column yields (Lemlich, 1968):

$$c_D = c_F + \frac{6.59G\Gamma_F}{d(F-B)} \quad [6]$$

and:

$$c_B = c_F - \frac{6.59G\Gamma_F}{Bd} \quad [7]$$

where Γ_F is the equilibrium surface concentration of the protein at the gas-liquid interface corresponding to the feed concentration. Since $\Gamma_F \geq \Gamma_B$, $B \leq F$, comparison of eqns [2] and [3] with eqns [6] and [7] indicates that the stripping mode yields a leaner bottom product and richer top product compared to the

simple mode of operation. The separation efficiency for a binary mixture is given by:

$$S = \frac{c_{D,2} c_{F,1}}{c_{F,2} c_{D,1}} = \frac{1 + \frac{6.59G\Gamma_2(c_{F,2})}{dc_{F,2}} \frac{1}{(F-B)}}{1 + \frac{6.59G\Gamma_1(c_{F,1})}{dc_{F,1}} \frac{1}{(F-B)}} \quad [8]$$

Analysis of Foam Column for the Prediction of Liquid Hold-up, Enrichment and Separation Factor

Various phenomena that take place in a foam column are shown schematically in Figure 2. Bubbles are formed by the sparger into the liquid pool. Proteins adsorb on to the bubbles during their formation and their passage through the liquid pool. The rate of adsorption of protein depends on the rate of diffusion of protein molecules to the gas-liquid interface as well as on the adsorption activation energy at the bubble surface. The extent of the surface coverage at the gas-liquid interface is dependent on the time of formation of the bubbles and its residence time in the liquid pool (Uraizee and Narsimhan, 1995). The foam bed consists of an assemblage of gas bubbles separated by thin liquid films, creating a large gas-liquid interfacial area. The size distribution of the bubbles depends on the type of sparger employed for bubble formation. A sintered disc with fine pores

Figure 2 Schematic of various phenomena that take place in a foam column.

usually results in a wide distribution of bubble sizes whereas either capillaries or orifices of uniform sizes lead to more or less uniform bubble sizes. Since the volume fraction of liquid in a foam is usually very small, the gas bubbles are distorted and are usually approximated by a dodecahedron (Narsimhan and Ruckenstein, 1986). A typical gas bubble is shown in **Figure 3A**. The neighbouring gas bubbles are assumed to be separated by planar films of the continuous liquid phase. Where three bubbles touch, their films drain laterally into a Plateau border. This is a channel whose length is the length of a side of the touching dodecahedral bubbles, and whose walls have a sharp concave curvature of radius R_p (Figure 3B). This lateral flow is caused by a pressure drop ΔP between the liquid pressure in the film, which is essentially the air pressure in the bubble, and the pressure of the liquid in the Plateau border. If σ is the surface tension of the bubble-liquid interface, then:

$$\Delta P = \frac{\sigma}{R_p} \quad [9]$$

The liquid in the Plateau border drains under gravity. Consequently, the liquid hold-up decreases with foam height. The lateral flow out of the thin films separating the gas bubbles will cause them to thin further, possibly causing them to rupture because of instability resulting from the growth of thermal and mechanical perturbations thus leading to bubble coalescence. Coalescence leads to internal reflux of the liquid from the ruptured films into the Plateau borders and a decrease in the interfacial area because of an increase in the bubble size. The former tends to enhance separation (enrichment) whereas the latter is detrimental. The former effect is usually predominant, so that coalescence leads to higher separation (enrichment). Only when coalescence is excessive, collapse of the foam bed occurs. When there is a broad distribution of bubble sizes, diffusion of gas from smaller to larger bubbles may occur because of the difference in the capillary pressure (being

inversely proportional to bubble size) thus leading to the growth of larger bubbles at the expense of smaller ones.

In order to predict the liquid hold-up as a function of foam height, one needs to solve the balance equations for drainage of liquid from thin films into the Plateau borders. The equations describing the rate of change, with vertical position, of the volumetric hold-up of the liquid in the films, caused by their drainage into the Plateau borders and bubble coalescence is given by (Uraizee and Narsimhan, 1995):

$$-\frac{d}{dz}(\eta n_f A_f x_f) - N n_f A_f V - \frac{N}{2} n_f A_f x_f \beta = 0 \quad [10]$$

where x_f is the film thickness, n_f is the number of films per bubble, A_f is the area of the film, η is the number of bubbles entrained per unit cross-section of the foam, N is the number of bubbles per unit volume of the foam, and V is the velocity of drainage of the film and β is the coalescence frequency. η and N can be related to the superficial gas velocity G , liquid hold-up ε , and the bubble volume v through:

$$\eta = \frac{G}{v}, \quad N = \frac{1 - \varepsilon}{v} \quad [11]$$

As before, the equation describing the rate of change, with vertical position, of volumetric liquid hold-up in the Plateau borders, caused by flow from the films into the Plateau borders and bubble coalescence, and gravity drainage is given by (Uraizee and Narsimhan, 1995):

$$-\frac{d}{dz}(\eta n_p a_p l) + \frac{d}{dz} \left(\frac{4}{15} N n_p a_p u R \right) + N n_f A_f V + \frac{N}{2} n_f A_f x_f \beta = 0 \quad [12]$$

Figure 3 Schematic of a bubble in a foam column.

where n_p is the number of Plateau borders per bubble, a_p is the area of cross-section of Plateau border, R is the radius of the bubble, l is the length of the Plateau border, and u is the velocity of gravity drainage of Plateau borders. Similarly, the protein balance in the foam can be written as:

$$-\frac{d}{dz}(\eta n_p a_p l c_{p,i}) + \frac{d}{dz}\left(\frac{4}{15} N n_p u R c_{p,i}\right) + N n_f A_f V_f c_{f,i} + \beta \frac{N}{2} n_f A_f x_f c_{f,i} + \beta \frac{N}{2} n_f A_f \Gamma_i = 0, \quad i = 1, 2 \quad [13]$$

where $c_{p,i}$ and $c_{f,i}$ are the protein concentrations in the Plateau border and film respectively. In the absence of coalescence, they would be equal. However, coalescence would enrich the liquid in the Plateau border because of reflux of adsorbed protein from the ruptured thin films. In the above equation, Γ_i is related to the bulk concentration c_i via the Langmuir adsorption isotherm given by eqn [5]. In eqns [12] and [13], V and u are the velocities of drainage of films and Plateau borders, respectively. For an immobile gas-liquid interface, the velocity of drainage of films into the Plateau borders can be evaluated from the Reynolds equation:

$$V = \frac{2 \Delta P x_f^3}{3 \mu R_f^2} \quad [14]$$

where R_f is the radius of the film, μ is the viscosity, and ΔP is the pressure drop under which the film drains. The velocity of drainage of the Plateau borders for immobile gas-liquid interface is given by:

$$u = \frac{\rho g a_p}{20\sqrt{3}\mu} \quad [15]$$

where ρ is the density of the liquid.

Eqns [10], [12] and [13] are initial value problems which have to be solved with proper initial conditions at the foam-liquid interface to evaluate x_f and a_p and $c_{p,i}$ as a function of foam height.

The liquid hold-up at the foam-liquid interface ($z = 0$) can be set to the void fraction of spheres (Uraizee and Narsimhan, 1995):

$$\varepsilon_0 = N n_f A_f x_{f0} + N n_p a_{p0} l = 0.26 \quad [16]$$

As the liquid hold-up at the top of the column is much smaller than 0.26, the flow rate at the top of the

column is much smaller than the entrainment of the liquid at the foam-liquid interface. Hence, the material balance around the foam yields:

$$\frac{G \varepsilon_0}{1 - \varepsilon_0} = \frac{4}{15} N_0 n_p a_{p0} u R_0 \quad [17]$$

The inlet bubble size R_0 depends on the type of sparger and the superficial gas velocity G . The above two equations can be solved for x_{f0} and a_{p0} . Also, the protein concentration in films and Plateau borders at the foam-liquid interface can be taken as equal to the pool concentration, i.e.:

$$c_{f0} = c_{p0} = c_B \quad [18]$$

The pool concentration should satisfy the overall protein balance given by:

$$F c_F = B c_B + T c_T \quad [19]$$

where F , B and T refer to feed, bottom and top product flow rates expressed per unit area of cross-section of the foam column. The overall mass balance can be written as:

$$F = B + T \quad [20]$$

Eqns [10] to [13] can be solved with the initial conditions [16] to [20] to give the profiles of x_f , a_p and $c_{p,i}$. The liquid hold-up ε at any foam height can then be calculated via:

$$\varepsilon = N n_f A_f x_f + N n_p a_p l \quad [21]$$

The enrichment e_i for each component is given by (Uraizee and Narsimhan, 1995):

$$e_i = \frac{(N n_f A_f x_{f,i} + N n_p a_{p,i} l c_{p,i} + N n_f A_f \Gamma_i)_T}{c_{F,i} \varepsilon_T} \quad [22]$$

where $(\dots)_T$ refers to the evaluation of the quantity within the parenthesis at the top of the column. The separation factor S is then given by:

$$S = \frac{e_2}{e_1} \quad [23]$$

The above analysis assumes adsorption equilibrium for the surface concentration of proteins at the

air–water interface. Uraizee and Narsimhan (1995) have modified this analysis to account for the kinetics of adsorption of proteins on to the gas bubbles during their travel through the liquid pool before the formation of foam and demonstrated the effects of different parameters including the kinetics of adsorption and pool height on enrichment and recovery of proteins.

Effect of Operating Conditions on Enrichment and Separation

The operating conditions that can be varied in a foam column are the superficial gas velocity G , the bubble size R , the column height L , feed flow rate F , the feed concentration c_f and the mode of operation. In addition, the separation will also be influenced by the viscosity of the feed and the extent of bubble coalescence in the foam column.

Protein enrichment depends on the total amount of protein selectively adsorbed at the gas–liquid interface as well as on the liquid hold-up in the foam. Smaller liquid hold-ups result in a larger interfacial area per unit volume of the liquid and therefore in larger enrichment. At higher superficial gas velocities, more liquid is entrained by the gas bubbles from the liquid pool leading to higher liquid hold-ups in the foam column and consequently to smaller enrichment. As the bubble size increases, a larger proportion of the liquid that is entrained by the foam is distributed in the film, resulting in a faster drainage rate. On the other hand, an increase in the bubble size results in a decrease in the interfacial area per unit volume. Because of the above two opposing effects, there exists an optimum bubble size at which enrichment may be maximum (Narsimhan and Ruckenstein, 1986) for one component protein solution as shown in Figure 4. In addition, this maximum is found to be more pronounced at smaller superficial gas velocities. Narsimhan and Ruckenstein (1986) have developed a population balance model to account for the bubble size distribution in the description of drainage and coalescence in a foam bed. Their model was able to predict the change in the bubble size distribution as a result of coalescence. The results indicated collapse of the foam bed for broader inlet bubble size distribution with a coefficient of variation above a critical value. In the case of a mixture of proteins, however, the separation efficiency would depend on the preferential adsorption of one protein over the other components as can be seen from eqns [22] and [23]. As expected, the separation efficiency is higher for the protein which adsorbs the most at the gas–liquid interface with a higher value of Γ . As a result, the separation efficiency

Figure 4 Effect of the inlet bubble size on the enrichment for $\mu = 10^{-2}$ P, $\mu_s = 10^{-4}$ sP, and $c_0 = 10^{-7}$ gmol mL $^{-1}$. (Reproduced with permission from Narsimhan and Ruckenstein, 1986a.)

would be higher for larger values of Langmuir adsorption parameter K_i as can be seen from eqn [5]. An increase in the viscosity of the feed would result both in a larger amount of liquid entrained by the foam as well as slower liquid drainage leading to larger liquid hold-up. Also, an increase in the viscosity of the feed would tend to stabilize the foam resulting in lower bubble coalescence. Both these effects will result in lower protein enrichment. Bubble coalescence in a foam column leads to: (i) an increase in the protein concentration due to internal reflux with subsequent increase in the surface concentration; (ii) a decrease in the liquid hold-up because of increased liquid drainage rates as a result of larger bubble sizes; and (iii) a decrease in the total surface area because of larger bubble sizes. The first effect results in more protein adsorption per unit area at the gas–liquid interface. The second effect leads to higher surface area per unit volume of the liquid. The third effect leads to a decrease in the total amount of protein adsorbed at the interface. Consequently, the first two effects lead to an increase in the enrichment and separation whereas the second and third effects lead to lower recovery. The second effect may be predominant since coalescence was found to result in an increase in protein enrichment as well as recovery (Uraizee and Narsimhan, 1995). The separation efficiency, as one would expect, depends on the relative

surface activities of proteins in a binary mixture. For larger values of Langmuir isotherm constant K_i (more surface active), the separation efficiency increases. In fact, the calculations show that the separation efficiency increases linearly with the ratio K_2/K_1 (Uraizee and Narsimhan, 1997). However, the separation efficiency was found to decrease rapidly with the feed concentration of the protein (Uraizee and Narsimhan, 1997).

Brown *et al.* (1990) measured enrichment and recovery in a continuous foam concentration column for bovine serum albumin (BSA). In their experiments, foam was generated by sparging nitrogen gas through a glass frit. As a result, the foam consisted of nonuniform size distribution of bubbles. They compared the experimental data with predictions based on a model similar to the one described above but neglecting drop coalescence. Their experimental data showed a decrease in the protein enrichment with superficial gas velocity. The model predictions agreed fairly well for the highest feed concentration of 0.1 wt% as shown in Figure 5. The experimental enrichments were found to be larger than the model predictions (even for the largest bubble size in the foam) with the deviation being larger at lower feed concentrations. This was believed to be due to the fact that drop coalescence in the foam column became increasingly important at lower feed concentrations as confirmed by experimental measurements of bubble size with the height of the column.

Uraizee and Narsimhan (1996) also observed a decrease in enrichment with gas velocity for foam concentration of BSA in their continuous foam con-

Figure 5 Effect of superficial gas velocity on protein enrichment for $c_F = 0.1$ wt%. $F = 0.02$ cm s⁻¹, $I = 0.1$ M, pH = 7, $z = 5$ cm. The curves refer to model predictions for different bubble sizes. (Reproduced with permission from Brown *et al.*, 1990.)

centration experiments in which the foam was generated by sparging nitrogen through a capillary bundle thus resulting in a foam of uniform bubble sizes. In their experiments, the residence time of the bubbles in the liquid pool was varied by varying the pool height. Interestingly, protein enrichment was found to increase with pool height at sufficiently high pool heights, thus indicating the importance of kinetics of adsorption of protein on to the gas-liquid interface on enrichment. At low pool heights, however, they observed an increase in protein enrichment with a decrease in pool height due to excessive bubble coalescence in the foam. Their model, which accounted both for the kinetics of protein adsorption as well as coalescence, was able to explain the increase in protein enrichment due to bubble coalescence at small pool heights and an increase in enrichment with pool heights at larger pool heights. A comparison of the experimental data with their model predictions is shown in Figure 6.

Ahmed (1975) observed an increase in the separation efficiency of albumin with the superficial gas velocity with the value reaching a plateau at sufficiently high gas velocities. Schnepf and Gaden (1959) and Ahmad (1975) reported a maximum protein enrichment at the isoelectric point of the protein which can be explained by the maximum protein adsorption at the interface due to the absence of electrostatic energy barrier for adsorption. However, this maximum was found to be considerably less pronounced at higher protein concentrations. Protein enrichment was also influenced by the change in the bubble size at different pH (Brown *et al.*, 1990). Separation efficiency of albumin was found to decrease dramatically as the foam height increased from 3 to 17 cm (Ahmed, 1975). Even though enrichment increased with foam height because of internal reflux resulting from increased drop coalescence, the top product flow rate was also found to decrease dramatically due to faster drainage. As a result, the protein separation was less at higher foam heights. Ahmed (1975) also found that the introduction of the feed stream into the foam instead of liquid pool increased the separation efficiency because the foam column was operated in the combined mode with an enricher and stripper.

In conclusion, the main attractive features of foam fractionation are its low capital and operating costs. Therefore, it can be employed as a first step for preconcentration/separation before more expensive separation methods can be used. More work is needed to establish the applicability of foam fractionation as a viable separation method for mixtures of proteins and to develop new processes based on this technique. Few experimental data are available on the adsorption isotherm and kinetics on to gas-liquid interface for mixtures of proteins. More importantly, it is necessary to probe denaturation (if any) of proteins and enzymes when subjected to foaming.

Introduction

The function of a flotation column is selectively to separate certain suspended solid particles or liquid droplets based on their surface properties. Bubbles rise and particles (drops) settle within the vessel, and collisions are highly dependent on gravitational momentum. The vessel is a multiphase contacting/heterocoagulation device where the dispersed phase to be removed attaches to the bubbles and accumulates at the top of the column in the form of froth. The latter overflows to launders. In this quiescent system, transport, dispersion and mixing of materials are induced by the motion of gas bubbles in the continuous liquid medium.

For the purpose of designing columns, immiscible liquid droplets are considered as acting as solid spheres of an appropriate size and density: thus, a 'particle' may represent either a solid or a liquid.

Almost all flotation columns are operated in the countercurrent regime where slurry moves downwards against a continuous rising bubble swarm. This type of flow increases efficiency (selectivity) of separation as the distance between discharge ports for overflow and underflow is large. In some cases, for example for the flotation of very coarse particles, co-current columns can be considered in order to increase particle residence time and reduce loaded bubble rise time. Unless otherwise stated, all of this article is related to countercurrent columns.

Initial Design Data

The feed transport fluid must be characterized in terms of liquid flow rate and chemical composition. Component solids or immiscible liquid flow rate, material composition and size distribution must also be known. In all cases, mean values, standard

deviations and design maxima and minima are required.

Test work must be done, or approximations made, to determine the flotation characteristics of the material to be separated, including rate constants and maximum recovery for all material and particle (droplet) size fractions. Process targets must be well understood, including the desired quality of products and recovery. Data error must be minimized since it directly impacts on the accuracy of the design scale-up.

Site-specific information is also required for final designs. This includes limitations in dimensions due to plant layout, civil engineering specifications, including such items as wind loading, earthquake considerations, supporting platforms and others.

General Dimensions

Typically, columns range in height from 6 to 15 m. This height is dictated by the dimensions of the different zones within the column but is most influenced by the collection zone height.

Column cross-sections are usually round or rectangular. Cylindrical columns do not have special flow conditions at the corners. They, therefore, usually have a more uniform air and feed distribution, less tank weight due to the self-supporting nature of the structure and less wall area per unit operating volume. Rectangular columns use floor space more efficiently and are easier to baffle. The cross-sectional area is usually constant throughout the vessel and is determined by carrying capacity and residence time considerations in the collection and froth zones. Typical industrial cell cross-sectional areas range from less than 1 m² to more than 12 m².

Column Zones

The flotation column, as generally built, is composed of a number of distinct zones. Under the spargers there is a dead volume (underflow zone) which is only used to remove slurry from the vessel. The volume between the spargers and the feed port is called the collection zone. The volume between the feed port

Figure 1 Column hydrodynamic zone.

and the froth interface is called the cleaning (recollection) zone and above the interface is the froth zone. The froth zone may be further divided into the washing zone, if it is under the wash water distributor, and the free drainage zone, if it is above. These zones are illustrated in Figure 1.

Underflow Zone

The physical dimensions of this zone should be minimized since its roles are to ensure that there are no small bubbles entrained by the downward flow to the underflow stream, that sloughing of the solids particles does not occur, and that the outflow from the base of the column does not create unwanted flow patterns within the active zones of the vessel. Bubble entrainment to the underflow is obvious, as in this case frothing occurs in the tailing sump or in the next open tank downstream of the column.

A zone underneath the spargers does not contribute to the floatation collection or separation. Design con-

siderations of the zone include base cone angle and placement, underflow exit port configuration and height to spargers.

Base Cone Design

In most solids separation applications, the base can be designed flat. The solids will eventually form a false bottom at the angle of repose under the specific flow conditions. Depth of the base cone should be selected considering angle of repose of particles. If sloughing of solids is considered a problem, then the column can be designed with either a real or false bottom at an angle greater than the angle of repose.

Underflow Port

Generally, the output port is designed to pull from the cross-sectional centre at the base of the vessel in order to minimize both the flow differences within the collection zone and large scale slurry circulation patterns.

The spargers are placed at a level such that the furthest descent of bubbles is above the highest expected solids settling point.

Collection Zone

The collection zone is characterized by a stream of individual bubbles rising against a descending liquid or slurry. This is the zone in which the bubble-particle attachment occurs. The capacity of the column is dictated in part by the intensity of bubble-particle collision (number of collisions per unit time), the probability of attachment, and the bubble surface area flux through the vessel (removal ability) in this zone.

When sizing a column, certain assumptions are made. These include that the column operates with dispersed bubbles that rise as a swarm without slugs. It is also assumed that the flow of bubbles, liquid and solids is uniform across the column, and that there are no large scale vortices.

There are four main collection zone design criteria which determine the vessel dimensions: floatable particle residence time, mixing characteristics, maximum gas rate and bubble loading. The resulting volume can usually be achieved with a range of height-to-diameter options. The final dimensions are also dictated by layout and economic considerations. It should be emphasized that this zone must be designed in parallel with the sparging system and froth zone as each of these parts influences the others. The placement of the column within the

operating circuit will also impact on the final design and operation.

Solids Settling

Particles settle within the column system since there is no mechanical agitation to suspend them. As such, each particle will have a specific hindered settling velocity dependent on size, density of the particle and the effective density and viscosity of the suspension with modifications due to bubble-induced mixing. Mixing enhances particle suspension, so small and/or light particles do not have their own trajectory and follow liquid flow more than in two-phase systems. The settling velocity generally has little influence on residence time for particles smaller than about 20 μm , but becomes an important design condition for larger particles.

Particle Residence Time Distribution (RTD)

Material residence time depends upon the inherent mineral settling velocity under the conditions within the column and the superficial velocity of the slurry. The total collection zone height divided by the summation of the hindered settling and slurry velocities gives a total average residence time for each particle size and density. More precisely, the particle residence time is a stochastic parameter influenced by the turbulent mixing and potential macrocirculation patterns within the column.

Elementary Processes

Flotation depends on the elementary processes of collision and attachment. In columns the probability of collision between a particle and a bubble remains virtually constant within the collection zone. There is a higher probability of attachment at the bottom of a countercurrent column since bubble surface coverage by particles is low for newly formed bubbles. This maximizes the recovery of the small proportion of particles targeted for flotation that are still present in the lower parts of the zone.

The relative movement of slurry and rising bubbles is the main source of mixing energy in columns. This results in a low intensity of the turbulence (low energy dissipation and large internal scale of turbulence) and, therefore, low relative bubble-particle velocities and accelerations. Bubble-particle collision efficiency is due to gravitational and inertial particle drift from the liquid streamlines around the rising bubble and due to the interception. The probability of particle detachment from bubbles is limited since the velocity gradient around the bubble is minimized.

Rate Constant

The floating ability of a material is generally referred to as a rate constant, similar to chemical processes, and is assumed (for simplicity) to be of first-order kinetics for each mineral component and size fraction. The value of this term is dependent on a complex function involving the collision/attachment and detachment, as well as processes occurring in other zones of the flotation column (see below). These data are generally determined through test work. As mechanism and intensities of subprocesses (collision, attachment, detachment, entrainment) in column and impeller flotation can be substantially different, the lab and pilot tests for column design and scale-up should also be made in columns. First-order flotation rates for the components can be determined from the recoveries in a continuous lab flotation column, or by simulation of kinetic tests by recycling column tails back to the feed line.

Taking into consideration separate first-order kinetic models for individual subprocesses and taking into account free bubble surface reduction in the upward direction would lead to complicated nonlinear kinetic equations. These are important in understanding the physics of the process, but cannot be used for scale-up or control, due to unavoidably high error in determining their coefficients from experimental data.

Carrying Capacity

The removal capability of the bubbles is called the carrying capacity and is the general term which characterizes the maximum amount of solids carried by the air bubbles (either in reference to the maximum capacity of the column, or to the maximum capacity per air volume). This refers to the fact that only a specific amount of particles can be attached to and removed by a certain bubble area. Thus, the maximum floatable solids removal or the surface area of attached particles is related to bubble surface area flux.

Typically, the distance between spargers and the slurry-froth interface is between 6 and 12 m. This leads to a substantial mass of particles attached to a bubble (bubble loading).

As bubbles become loaded by collected particles, the contact time between particle and bubble reduces due to the shortening of particle trajectory along the free bubble surface. This means that the rate of collection slows as loading increases, especially when the lower section of a bubble is virtually covered by attached particles. Detachment probability is also much higher for particles attached to the upper hemisphere of a bubble.

Smaller bubbles can carry more solids than larger bubbles, assuming an equal gas rate and that the loaded bubbles have sufficient buoyancy to move against slurry flow. A smaller weight of fine particles can be carried at a constant gas rate and bubble size distribution than that of coarse particles.

Carrying capacity limitations should be taken into account when estimating height-to-diameter ratio for columns working at high overflow (froth) yield. Typical carrying capacity per unit column cross-sectional area for base metal minerals flotation is $2.5 \text{ t}/(\text{m}^2 \text{ h})$ and for coal flotation $1.5 \text{ t}/(\text{m}^2 \text{ h})$.

Gas Rate and Bubble Size

Column cells are operated in the bubbly region where bubbles rise in a swarm. The flow regime in the column may change to the 'churn-turbulent' condition when coalescence is caused by gas entering a region faster than it can leave as small bubbles. As smaller bubbles have lower swarm rising velocity, the flooding occurs at a lower gas rate for fine bubble dispersions. Thus, there is a link between maximum gas rate at the flooding point and bubble size. Also, flooding is enhanced by countercurrent slurry flow; the higher its superficial velocity, the lower the gas rate at the flooding point. At bubble size ranges used for column flotation, flooding occurs typically at a superficial air velocity of $2.5\text{--}3 \text{ cm s}^{-1}$. More precise values can be calculated from the drift flux model.

It is also possible for uniform countercurrent froth flow to occur in the column even at lower superficial air and slurry rates when the bubbles are very stable (gas hold-up at both bubble and froth flow regimes can also be estimated based on the drift flux model).

Mixing

Columns are commonly sized with a dispersion method which uses the Peclet number, a dimensionless criterion, to characterize mixing. It is assumed that an axial dispersion model adequately reflects flow structure in the collection zone. It is also possible to use a tanks-in-series flow model. The Peclet number reflects the ratio between the downward path of particle and the average length of its stochastic drift due to mixing (diffusion). It is equal to UL/D , where U is the mean velocity of the phase of interest (for particles it is the sum of downward liquid velocity and a hindered settling velocity), L is the characteristic length scale for the apparatus (collection zone height of the column), and D is the turbulent dispersion (diffusion) coefficient. The latter can be determined by a tracer technique or by using one of

several approximation formulae. D ranges from 0, for perfectly mixed systems, to infinity, for plug flow. The following variables have an effect on the Peclet number: bubble size and number of bubbles (which are dependent on gas rate and surface tension), slurry rate, particle settling velocity, collection zone height and diameter. At a constant collection zone volume, a taller column is better from a flow structure perspective as less mixing is induced. Peclet number can be estimated using one of the experimental relationships, or from particle residence time distribution (RTD) similar to that in chemical reactors or separation equipment. RTD can be directly measured using a tracer method. Dispersion of the RTD can be used to calculate turbulent diffusion D and other column flow structure criteria.

The absence of an agitator limits the formation of large scale flow loops unless the column is operated in a high air rate, churn-turbulent flow or the feed distribution of either air or slurry is not even. Low mixing intensity and lack of circulation contours cause particle residence times to be highly dependent on the particle settling velocity. Reduced mixing leads to lowering of local upward flow intensities which minimizes particle entrainment to the froth. Thus, at a constant collection zone volume (slurry retention time), its increased height leads to lower mixing intensity and improved (due to this) metallurgical results up to the point when restrictions in carrying capacity limits concentrate (float product) yield. Also, higher superficial slurry velocity reduces negative influence of mixing and slime entrainment intensity.

Careful design and positioning of any baffles (horizontal or vertical), the feed system, and any internal piping that may be needed minimize local turbulence. The feed pipe must be located high enough in the column to maximize the collection zone length but also low enough to limit turbulence at the slurry-froth interface.

Entrainment

Fine and/or light hydrophilic particles may pass upwards through the collection zone by entrainment. There are two forms of entrainment. In the first, a portion of feed water containing suspended fine particles passes into the froth. This type of entrainment can be minimized by maintaining a net downward flow of water through the upper column zones. The second form of entrainment is the capture of particles in the eddies behind a rising bubble. These particles are also rejected in the froth zone operating with positive bias.

Baffling

Columns may be vertically baffled in order, both to reduce mixing and to lend additional structural support. An important condition to achieve effective operation with a baffled column is an even feed and air distribution between the compartments, otherwise detrimental circulation patterns may form between the baffled sections. This overall circulation can make a baffled column less effective in terms of flow structure than a column without baffles. Normally, baffles are installed above and below the feed distributor in a column, leaving space around feed pipe(s) and air spargers open to allow even distribution of the slurry and air bubbles, respectively.

Horizontal baffles (plates) are not typically used, though tests have confirmed their ability to improve flotation of coarse particles due to less short-circuiting in the wall part of the baffled column.

Physical Dimensions

The total volume of the collection zone is determined by residence time considerations, having also accounted for mixing and hindered settling of coarse particles, to achieve target recoveries. A formula based on an axial dispersion model and first-order flotation kinetics is typically used. A minimum diameter is then calculated to allow sufficient bubble surface area to float the required solids. The diameter and height must be larger than these minimum numbers and any combination can be used as long as the volume remains above its minimum. The volume should provide for the necessary retention time with a correction for mixing, but should not exceed it substantially. This is critical in the case of selective flotation when both components are floatable and have different but nonzero rate constants.

The selection of the vessel dimensions is an iterative process since a change in many of the variables will change the overall mixing in the vessel.

Access

Periodic maintenance is required, and access to the inside of the column may be needed. Therefore, access manholes and appropriate clearances must be maintained within the vessel.

Cleaning Zone

The purpose of this zone is to buffer the froth zone from the turbulence of the feed port. It is located above the feed port and below the interface with the froth. It is characterized by rising bubbles that may be highly loaded with solids rising from the collection zone and falling solids that have been entrained in the

bubbles' wake, or have been rejected in the froth zone by loss of bubble surface area. If a sufficient amount of wash water is used, this zone may have a net downward flow of slurry. Only a limited number of previously uncollected particles occurs in this zone due to the turbulent mixing or entrainment. Since collection of these particles can also occur in the collection zone, the height of the cleaning zone should be minimized but must be sufficient to allow damping of the feed turbulence below the froth interface.

In some circumstances the cleaning zone is the overflow point of the float product. This occurs when there is no froth zone either because a froth cannot be maintained in a solids float, or because a liquid-liquid separation is being performed. In the latter case an organic pad may be present.

Froth Zone

This zone is usually present in solid-solid or solid-liquid separations.

The froth zone in a column cell is characterized by a rising bed containing a matrix of bubbles, which are loaded with hydrophobic material, water lamellae between bubbles and Plateau-Gibbs canals. Entrained hydrophilic material may be found initially either in lamellae or in canals. Film (lamella) thinning and bubble coalescence in froth (syneresis) and drainage in Plateau-Gibbs canals are the main mechanisms of gas hold-up increase and concentrate upgrading with height in the froth. This is caused by reduction of the air-liquid interface area and subsequent particle detachment. Tracer tests indicate that, in some cases, more upgrading is observed within the froth than between slurry and lower froth layers.

Quiescent conditions in columns create a stable froth that allows the addition of wash water. This water displaces the liquid phase of the feed slurry, with entrained associated fine particles, from the froth lamellae and Plateau-Gibbs canals and allows the production of an essentially entrainment-free overflow. In some cases, addition of small amounts of water into the froth also improves the stability and rheological properties of the countercurrent froth.

A presence of highly hydrophobic, angular particles large enough to bridge the lamella between bubbles, without a population of smaller hydrophilic particles, causes froth destabilization. In this case the froth zone design is critical. In extreme cases a froth bed may not be possible.

Channelling

Uneven distribution or excessive addition of wash water can cause formation of channels in the froth

and possible froth collapse. Care must be taken in the design of the distributor to ensure even cross-sectional wash water flows.

Froth Zone Dimensions

Although the froth zone usually has the same cross-sectional area as the collection zone, it may be necked to promote crowding which increases the upward velocity in the froth. This may be done when small amounts of froth are generated, reagent conditions dictate that the froth will not be stable, or the size distribution of solid particles in the froth promotes coalescence of bubbles. It is more common to preserve the overall area and apply internal baffling and launders. Internal baffles may be added to support the froth, or to contain or localize froth collapse.

Internal Launders

Syneresis and coalescence occur within the froth zone. Thus, relative to a localized section of froth, bubble surface area is lost with time as that section travels from the slurry-froth interface to the overflow points. Furthermore, analysis of particle RTD in froth indicates that horizontal transport to the froth launder is very slow. For larger diameter columns, dead zones can form in the central part of the vessel. Columns normally do not have froth skimmers or paddles. Therefore, fast froth removal is critically important for operation and is often achieved by a series of internal froth launders.

Organic Pad

Liquid-liquid column applications may be operated with an organic pad on the top of the vessel. Organics floated in the collection zone gather at the surface of the vessel. These may overflow a weir continuously if the organics concentration is sufficient or if low concentrations of organics in the overflow stream are acceptable. Otherwise, the pad accumulates and is dumped on a regular basis. If some or all of the organic compounds present in the system are volatile, a pad may not be suitable or dumping must be frequent to prevent excessive stripping.

Air-Sparging Systems

The purpose of the sparging system is to distribute evenly the appropriate-sized bubbles near the bottom of the column. The sparging system is critical and must be designed taking into consideration many elements, including bubble size distribution, maximum air rate, bubble coalescence and induced mix-

ing; uniformity of air hold-up across the vessel, minimization of scale formation, resistance to wear, required air pressure and maintenance considerations.

There are many types of spargers used in column cells. Pneumatic (porous media or perforated) spargers form bubbles at small orifices. Pneumohydraulic spargers break up an air stream into bubbles by a water jet as an air-water mixture is distributed into the column. The air jet spargers form bubbles through the high velocity injection of air into the column. There are also a class of spargers termed external spargers that aerate the feed slurry, or portion of the underflow, and use the column as a de-aeration or bubble separation vessel rather than for particle collection. Combination of external spargers for slurry pre-aeration with microbubbles and/or dissolved air with internal spargers to facilitate microbubble buoyancy by adding larger bubbles is optimal for a wide range of applications (see below). In recent years, the general trend among major column suppliers is to use air jet and external types of spargers, although specific circumstances dictate the use of other types.

Care must be taken when designing the bubble distribution system to ensure that an even flow of bubbles is generated. Poor air distribution can cause large scale flow patterns in the column that are detrimental to performance. Macrocirculation zones can also be caused by a misalignment of the column either by bows along the length or by offsets from the vertical.

Pre-Aeration

Columns, by nature, have low turbulent momentum between the bubbles and particles, meaning that smaller particles have slow flotation kinetics in these vessels. The column is, however, a good separator of bubbles from the feed slurry, especially if wash water is added. This feature virtually eliminates hydrophilic entrainment. In order to improve the collection of fine particles, a pre-aeration system or intense flotation device can be used. These devices act by creating a turbulent zone, where the inertial momentum of both bubbles and particles is high (due to high intensity turbulence and velocity gradients) enabling higher recovery of the smallest floatable particles by microbubbles. If the pressure in the pre-aeration device is substantial, a portion of air is dissolved and then released in a column; normally, nucleation of air bubbles occurs at a solid surface, thus a collision stage of flotation process is eliminated for the cavitation bubbles.

Pre-aeration devices then feed a modified column which acts as a recollection device for the larger particles and a bubble coalescence/separation system.

Civil Engineering and Material of Construction

The final column design must be site-specific. There may be height and/or area considerations due to restrictions of space, and weight and loading considerations due to foundation requirements. In addition, some environmental considerations such as wind load, earthquake zone and rainfall intensity will affect steel thickness, foundations and attachments, braces and access platforms. As columns are normally much taller than mechanical flotation cells, they are often located outside, and these factors can play an important role in column design. There are also process considerations like per cent solids, wear factors, chemical composition of the slurry (pH, etc.) and particle size distribution which affect the physical structure, pipe sizing and materials of construction. In special cases, these units may be designed as pressurized vessels or as enclosed systems.

For example, many oil–water separation columns are pressurized or some installations use circulating inert gases to minimize oxidation. When columns are installed for oil–water separation duties, mainly on offshore platforms, a circulating hydrocarbon gas (propane) is often used instead of air.

Conclusions

Despite its simple design, the scale-up and modelling of column flotation is a complex problem. It includes analysis of three-phase three-dimensional flow in collection and cleaning zones and in the washed thick froth layer. In the last few years, a technique for column design has been developed. Its adequacy has been confirmed by many columns installed worldwide for a wide range of mineral and other applications.

Special attention should be paid to the carrying capacity of air bubbles and to secondary upgrading in the froth.

Design of air-sparging systems, feed distributors and also froth discharge systems is critically important for successful column operation.

Unconventional design and use of pre-aeration systems are the main trends in flotation column development at present.

Flotation is a versatile, surface wettability-based separation process, usually taking place in an aqueous medium. In flotation, a water-repellent (hydrophobic) target to be separated is attached to a carrier lighter than the medium in which separation occurs. The target varies from fine particulates (solid or

liquid) to ions and molecules, while the most commonly used carriers are air bubbles due to their ready availability, easy handling and very low cost. Compared to other light fluids (e.g. paraffin oil), air has the highest hydrophobicity, and its low density facilitates mass transfer of bubble-target aggregates from the bulk medium to the interface where froth forms and is collected/removed. Flotation was practised around a century ago, mainly for mineral separation applications. It is difficult, if not impossible, to pin down who should be given credit for the

Table 1 Key stages in flotation process development

Year	Concept introduced	Inventors

1925	Modern flotation collectors (xanthate for sulfides)	Keller

development of the flotation process in the various key stages. Nevertheless, **Table 1** provides a general picture of how flotation has evolved since its first applications in mineral processing.

As shown in this table, up until the 1930s all the ingredients required for selective flotation had been proposed, including: (i) a collector to render target particles water-repellent by its adsorption; (ii) a frother to stabilize bubbles and promote foaming; (iii) an activator to induce or enhance collector adsorption on target particles; and (iv) a depressant to destroy collector adsorption on unwanted particles; along with bubble generation in a flotation machine.

Figure 1 A flotation system shown as a tetrahedron with chemical, mechanical and physical aspects as the foundation through which process dynamics is modelled and controlled. The triangular base plane emphasizes the interrelated nature between the three foundation elements. The chemical aspect involves control of chemistry at air- and solid-aqueous interfaces by collectors, depressants, dispersants, activators, bacteria and frothers; the mechanical aspect concerns energy dissipation for bubble generation, particle dispersion, surface cleaning, hydrodynamic forces and bubble-particle contact; the physical aspect deals with the wetting phenomena and the nature of interactions between bubble-particle, bubble-bubble and particle-particle pairs in aqueous solutions involved in a flotation system.

These ingredients form one of the three foundations on which a flotation system is built. This is shown in **Figure 1** as flotation chemistry. Although neither the principles involved in flotation nor these basic ingredients have been changed since, the technology along with the fundamental understanding of the processes have evolved greatly. Developments in each of these three foundations are summarized in this article with emphasis on recent advances.

Flotation Chemistry

The search for new flotation reagents for various mineral separation systems has been one of the major aims in flotation chemistry development. Although xanthate, first used more than 70 years ago, remains the principal collector for sulfide mineral flotation, long chain surfactant has been introduced as the collector in oxide, silicate and sparingly soluble salt mineral flotation systems. The early trial-and-error approach in screening and searching for a new flotation collector has evolved into today's scientific design. Using quantum chemistry and electron density calculations, the structures of highly selective collectors have been proposed. A surfactant, with oxygen and nitrogen as the binding elements in its functional group (e.g. hydroxyoximes), was found to be a powerful and more selective collector for oxide minerals, while those with sulfur and nitrogen as the binding elements (e.g. thionocarbamate) is particularly selective for sulfide minerals. A common feature of these new collectors is their electron donor character, forming a five- to six-member closed ring structure with surface metallic elements. Many five-membered heterocyclic compounds (e.g. oxazole- or thiazole-based collectors) have recently been found to be of special selectivity in base metal ore flotation. A general correlation between flotation performance and collector chain structure (e.g. short versus long, single versus double, straight versus branched, single bond versus double bond, paraffinic versus aromatic, etc.) has also been established and a detailed list of newly developed collectors was compiled by Nagaraj in 1988. The use of a collector mixture has shown improved collecting power and selectivity, and warrants further development.

The invention of a water-soluble frother by Tveter (a polypropylene glycol ether, known as Dowfroth) was considered to be one of the major advances in frother development. Following the advent of various types of synthetic, propylene-based frothers, the effort in frother development has been directed to establishing a correlation between frother structures, frothing characteristics and their effect on recovery and selectivity. To this end, increasing branching

in frother molecules has been identified as increasing flotation selectivity, often at the cost of reduced recovery. The use of mixed frothers in a flotation system to generate air bubbles with a wide range of sizes, each suitable for particles of a given size range, has also drawn considerable attention. An increased overall recovery has been demonstrated by using a mixture of 1:1 polyglycol:methyl isobutyl carbinol (MIBC) as compared to a single frother at the same total concentration level. The synergistic effect of a collector and a frother on bubble-particle collection has also been recognized, although the practical application has not gained its fair share of attention. The stabilization of air bubbles by simple inorganic electrolyte should not be overlooked. Developed in the early 1930s for natural hydrophobic coal flotation without using a frother, salt flotation provides a different avenue for recovering natural hydrophobic minerals, as the surface active frother tends to adsorb on natural hydrophobic minerals with unfavourable orientations for flotation, consuming added chemicals and reducing their floatability. In 1995 Weissenborn and Pugh confirmed that the hydration shell around the added inorganic (ionic) species or frother's polar groups is responsible for froth stabilization.

Development in the activator appears rather limited, although most of the positively charged metal hydroxy species have been found suitable for activation in silicate flotation. In sulfide flotation, copper sulfate remains the only activator extensively used today. In contrast, development in depressants has taken on a different pace. Shortly after the introduction of sodium dichromate (for PbS) and SO₂ (for ZnS) in 1913, sodium cyanide (1922) and alkali sulfites (1923) appeared to be the popular depressants to use and remain the major depressants in modern sulfide flotation plants. Meanwhile, sodium silicate (1928) and macromolecular starch (1931) have become important depressants/dispersants in oxide, silicate and sulfide flotation systems. In addition to nonionic dextrans, cationic polysaccharides and anionic carboxymethyl cellulose have been found to be effective depressants because of their multi-anchoring nature with mineral surfaces. Recent efforts have been directed to the search for polyamines, which are effective in iron sulfide depression, driven by the environmental pressure of reducing SO₂ emission from smelters. Combined with SO₂, diethylenetriamine (DETA) has been found effectively to depress the pyrrhotite in pentlandite flotation, although the depression mechanism remains to be identified.

The control of the mineral surface property by biotreatment is an emerging area and represents a special branch in flotation reagent development.

This approach is of special importance for desulfurization in coal flotation, selective depression in base metal sulfide flotation and hydrophobization of non-sulfide minerals. The success of biotreatment in these systems lies in the extremely high selectivity of bacteria, such as *Thiobacillus*(T-)*ferrooxidans*, towards the oxidation of pyrite, without any adverse effect on the flotability of coal, resulting in a high desulfurization efficiency in coal flotation. Also reported is an improved floatability of sphalerite by pretreatment of T-ferrooxidans in an acidic medium. However, a high dose of T-ferrooxidans has been found to be detrimental to sphalerite and galena flotation. Although sulfate-reducing bacteria have a minimal effect on the floatability of molybdenite and galena, they have been found to depress the floatability of chalcopyrite and sphalerite, resulting in highly selective flotation. Brunet *et al.* (1998) reported that the combination of T-ferrooxidans, T-thiooxidans and *Leptospirillum* accelerated pyrite oxidation. The high selectivity of a bioprocess warrants the rapid growth of biotreatment in mineral flotation.

Accompanying the development of various flotation reagents is the recognition of surface reactions/adsorption and the understanding of collector/mineral interactions in selective flotation. The theory of sulfide flotation with xanthate family collectors has advanced from simple surface chemical reactions to a generalized electrochemical-chemical process. Recognizing the electrochemical nature of collector adsorption on sulfide surfaces was a quantum leap in sulfide flotation chemistry. The application of the mixed potential theory to a sulfide flotation system provides a scientific explanation for a required oxygen level to induce the floatability, and accounts for the role of pulp electrochemical potential (Eh) in sulfide flotation for a given collector chemistry. An important consequence of electrochemical involvement in sulfide flotation is the development of self-induced (also known as 'collectorless') flotation by either controlled oxidation or sulfidization of pre-oxidized sulfide minerals. The use of cyclic voltammetry allows a direct correlation between collector adsorption (determined by charge integration), under a given applied electrode potential, and contact angle, which in turn determines the floatability of sulfide minerals. An important outcome from electrochemical studies is a new mechanism for differential flotation of complex sulfides by pulp potential control. However, the controversy regarding the collector reaction product on sulfide minerals is yet to be resolved. To this end, modern spectroscopic methods are useful. Surface reactions have been studied extensively using various surface analytical techniques, including: (i) Fourier transform

infrared spectroscopy (FTIR in both *in situ* and *ex situ* modes); (ii) Raman spectroscopy; (iii) Auger and X-ray photoelectron spectroscopy (AES and XPS); (iv) fluorescence spectroscopy; (v) electron spin resonance spectroscopy; (vi) laser ionization mass spectrometry (LIMS); and (vii) time-of-flight-secondary ion mass spectrometry (TOF-SIMS). For example, the monolayer formation of polysulfide as a sulfur oxidation product on PbS has been confirmed from synchrotron XPS characterization. However, whether or not polysulfide is responsible for collectorless flotation remains to be established. Following the pioneer work on *in situ* spectroelectrochemical characterization of sulfide flotation chemistry by Leppinen *et al.* in 1988, the development of a spectroelectrochemical cell (Figure 2), combined with polarized FTIR spectroscopy, sets up an entirely new direction for sulfide flotation chemistry research. Using polarized infrared radiation, the orientation of the adsorbed molecular species can be derived, as shown in Figure 3. However, further research efforts are required to quantify the mo-

lecular orientation and to derive its practical implications in sulfide flotation practice.

In oxide and silicate mineral flotation, the interaction (i.e. adsorption of the collector, mostly surfactant) has been generally considered to be electrostatic rather than chemical in nature. An electrostatic interaction model has proven satisfactory when applied to silica and alumina flotation with ionic collectors of opposite charges from the surfaces. Progress has been made in predicting the point of zero surface charge, based on the minimum solubility theory and the sign of surface charge from the hydration energy of lattice ions. A more quantitative description of surface charge distribution has been made possible following the development of the surface triple-layer model in combination with the surface site-binding theory. Early adsorption studies have revealed the formation of surfactant hemimicelles on mineral surfaces at a bulk surfactant concentration of approximately one-hundredth of its critical micelle concentration (cmc). The formation of ionomolecular complexes has been found to enhance the floatability of oxides.

Figure 2 Schematic diagram of an *in situ* spectroelectrochemical cell suitable for studying sulfide flotation chemistry. Pushing a movable sulfide mineral working electrode against the CaF₂ window with a screw type of mechanics ensures not only elimination of bulk water films to increase the sensitivity of infrared spectroscopy, but also reproducible positioning of the electrode (after each electrode polarization) for quantitative analysis. The use of polarized infrared radiation in external reflectance mode allows identification of molecular orientation.

Figure 3 *In situ* infrared spectra obtained with a copper electrode polarized under electrode potentials of 150 (dotted lines) and 350 (continuous lines) mV/SHE (standard hydrogen electrode) in 2×10^{-3} mol L $^{-1}$ potassium ethylxanthate solutions. By comparing the spectra obtained with s- and p-polarized infrared beams, a near perpendicular orientation of adsorbed copper xanthate on copper electrode (inset) was derived to account for the absence of the band at 1050 cm $^{-1}$, associated with COC molecular vibrations, with the s-polarized infrared beam. In contrast, a random orientation of dixanthogen, formed under a higher applied electrode potential, was ascertained by a similar spectral feature of characteristic dixanthogen bands obtained with both polarization modes.

This is consistent with recent observations on enhanced hydrophobicity of mica surfaces in a mixed cationic amine and neutral alcohol surfactant solution. The increased overall surfactant adsorption density at the solid-liquid interface is accounted for by screening electrostatic repulsion between adjacent surfactant head groups.

Recently, a detailed study using a well-defined basal plane of crystalline sapphire in a surface forces apparatus showed that the formation of monolayer hemimicelles requires a near-cmc surfactant concentration in the surface region, while its bulk concentration has to be well below the cmc. Based on the well-known Stern-Grahame equation, this condition

cannot be satisfied in the absence of any attractive driving force of electrostatic and/or chemical nature required to preconcentrate the surfactant in the surface region to the cmc level. As a result, the lack of hydrophobic monolayer formation and hence effective flotation is anticipated.

Clearly, effective oxide flotation requires creation of a chemical environment that maximizes the surface concentration of the surfactant at as low a bulk concentration as possible. Changing suspension pH to control surface charge density in oxide flotation serves as an excellent example. Under certain circumstances, activation by hydrolysed metal ions, which provide the linkage between an anionic collector and a negatively charged mineral, is necessary to induce floatability. It should be noted that the selectivity of separation in oxide flotation is relatively poor if the electrostatic force is the only driving force for collector adsorption. This is particularly true in fine particle flotation, as heterocoagulation between different minerals often induces a secondary locking which destroys the selectivity. To this end, searching for collectors which chemically anchor on to targets remains the focus in oxide flotation systems. For sparingly soluble mineral flotation, solution chemistry calculation has been proven to be one of the most valuable tools in searching for separation windows. Since bulk solution chemistry controls the flotation response, a bulk precipitation followed by surface deposition, with a switch-on type of adsorption characteristics, has been considered to be the most favourable mechanism in flotation of soluble-type minerals, where the monolayer adsorption is hardly recognizable.

A recent trend in laboratory studies of sulfide flotation chemistry is to use a mixed mineral system. With this approach, an enhanced xanthate adsorption on anodic minerals by galvanic contact of dissimilar minerals was revealed. Also derived from this type of research is the depression of pyrite by copper sulfate addition in a sphalerite/pyrite mixed mineral system, shown in **Figure 4**, as opposed to pyrite activation in a single mineral system. A similar approach has been used in oxide and salt-type flotation systems.

In summary, our understanding of the interaction mechanism of collectors with minerals in a flotation system has evolved significantly following the development of modern instrumentation. Future advances in the fundamental understanding of flotation systems are anticipated with the introduction of the atomic force microscope in mineral flotation research. A combination of electrochemistry, *in situ* spectroscopy and surface imaging at a molecular level will enable us to pinpoint the mechanism and roles of collector-mineral interactions in flotation.

Figure 4 Flotation recovery of pyrite in the presence of 10^{-5} mol L $^{-1}$ iso-propylxanthate alone (squares) or with cupric ions (triangles), sphalerite (inverted triangles) or both (circles). The flotation of pyrite was depressed by a combination of cupric ions and sphalerite, although cupric ions alone activated pyrite flotation, illustrating the importance of studying flotation chemistry with mixed mineral systems in the context of the separation practice.

Flotation Mechanics

Bubbles are an indispensable component of froth flotation. Bubble generation in flotation machines forms the second foundation of a mineral flotation system. It is interesting to note that the development of flotation machines follows the evolution of bubble generation methods, although a flotation machine has to fulfil three basic functions: (i) generation of sufficient amount of bubbles with suitable sizes (c. 0.5–2 mm); (ii) dispersion of solid materials; and (iii) effective collision between particles and bubbles, in addition to providing a quiescent zone for froth formation. **Table 2** summarizes the major steps in the early stages of flotation machine development. Up until 1911, all available bubble generation methods had been practised in flotation machines. Driven by

an increased demand for metals and a need for cost reduction, the development of flotation machines in the subsequent 50 years was directed to the design of large volume cells, with the benefits of flexible process control and reduced capital cost, plant space, specific power and maintenance. Taking DO-3500 (Denver) as an example, cells of volume as large as 100 m 3 are now in operation. Radical changes incorporated in this new super-large cell include the use of a pump-type rotor, an overhung vane-type stator, a round tank of conical bottom and radial discharge of froth as in flotation columns. The most recognized development in flotation machines today is, however, the commercialization of flotation columns, followed by various innovative designs of aeration systems to generate microbubbles in response to slow flotation kinetics of fine particles.

The success of conventional flotation columns initiated a surge in the development of novel flotation devices, some of which are summarized in **Table 3**. Detailed analysis of these new devices shows a common feature – the generation of fine bubbles online with high energy dissipation (e.g. high turbulence in fluid). Major advances in these devices are illustrated, for example, in a fast flotation column, shown in **Figure 5**. The in-line generation of fine bubbles (feed aeration) by either a static mixer or a simple Venturi tube ensures a high bubble–particle collision efficiency. Partial recycling of tailings to the feed allows fugitive valuables to be captured, while a deep froth with wash-water addition cleans up entrained unwanted gangues. Essentially, a flotation column in this configuration is equivalent to a flotation circuit: (i) a rougher in the middle; (ii) a cleaner on the top; and (iii) a scavenger at the bottom.

The improvement of froth quality, by deep froth and froth washing in the flotation column, brought the recent development of Outokumpu's HG tank, which features an adjustable booster cone to control froth quality. A hidden feature in these newly designed flotation devices is the role of hydrodynamic cavitation. The importance of hydrodynamic cavitation in flotation is the complete elimination of the bubble–particle collision step, resulting in a 100% increase in flotation rate constant, seen in a case study using the set-up shown in **Figure 6**. The preferential nucleation of bubbles on hydrophobic particles is anticipated to contribute to improvement in flotation selectivity. With hydrodynamic cavitation, strong mechanical agitation, which is otherwise required to provide the kinetic energy necessary to overcome energy barriers for bubble–particle attachment, can be minimized. As a result, a more quiescent environment is created for enhanced froth–pulp disintegration. Along the same line of thinking, the use of

Table 2 Early developments in bubble generation and flotation machines

ultrasonication or vibroacoustic modulation, to facilitate gas nucleation and bubble–particle attachment, has been tested. A gas nucleation mechanism, most likely by hydrodynamic cavitation with innovative engineering of the cavitation tube or ultrasonic modulation, is anticipated to be the main feature of the next generation of flotation devices. A reactor–separator design as seen in Figure 5 is desirable to optimize individually bubble–particle contact and bubble–pulp separation.

Flotation Physics

It is evident that, for effective flotation, the thin liquid films between an air bubble and a target have to be thinned and ruptured (film stability), while association between different species (hetero-coagulation) needs to be avoided to separate one species from another. The physics of the flotation system (i.e.

surface forces between various phases) controls such phenomena as thin film stability and coagulation. As a macroscopic process, flotation is often analysed in terms of micro subprocesses and the knowledge about them would serve as an encyclopedia of colloidal science. Fundamental studies in flotation physics have evolved, to today's role of hydrophobic forces in flotation, from pioneer work by Wark (capillary forces), Sutherland (contact angles), Derjaguin (interparticle forces), Derjaguin and Dukin (elementary stages of flotation), Klassen (role of hydration shells in flotation), Scheludko (thin film stability) and Schultz (hydrodynamic forces).

The capillary phenomena confirmed the existence of relatively short range molecular forces, manifested in observed surface tension. The floatability of minerals has been frequently correlated to contact angles of solid against water (or, more precisely, contact angle hysteresis in flotation practice, which involves

Figure 5 Schematic of a modern flotation column featuring feed line aeration (insert) and partial recycle of tailings. The main thrust of a column in this configuration is its equivalence to a virtual flotation circuit with the capability of generating fine bubbles for fine particle flotation.

Figure 6 Schematics of a flotation system with reactor-separator design exploiting hydrodynamic cavitation in fine particle flotation. A 10-fold increase in removal efficiency of fine oil contaminants in the soil-washing process has been demonstrated in a laboratory-scale test. Using the setup at INCO's Matt separation site (Sudbury, Canada), a doubling of the pentlandite flotation rate at a comparable concentrate grade was obtained. The main attraction of this configuration is that it can be readily implemented in the existing flotation circuit by simply bridging the conditioning tank with mechanical cells using a cavitation-type reactor.

consideration of both adhesion and detachment). The contact angle phenomena manifest the competition for water molecules by solids and by water itself, assuming that the interaction between air and other phases (solid or water) is negligible. The work of cohesion of water greater than the work of water-solid adhesion is equivalent to a contact angle greater than zero as the thermodynamic criterion of floatability. However, the former provides insight into the competition between various phases. Analysis on work of adhesion and cohesion for a flotation system has contributed to the improved understanding of flotation physics. To this end, the concept of critical surface tension proposed by Zisman was adopted in a so-called Gamma flotation process, although its practical application has been limited to coal flotation or the recycling of low surface energy polymeric materials. The role of collector adsorption in flotation is to reduce the work of adhesion of target solids by exposure of weakly interactive hydrocarbon tails to water. Such a system of high solid-liquid interfacial tension is thermodynamically unfavourable, making the particles floatable.

The use of the electrostatic double layer and van der Waals forces considered in the classical colloidal stability theory (known as Deryagin-Landau-Verwey-Overbeek, or DLVO theory) has been suc-

cessful in accounting for the stability of some colloidal systems. It is now generally accepted that additional forces need to be considered to understand fully the observed phenomena in flotation systems. A typical example is that alumina is not floatable in the absence of surfactant, although a strong electric double-layer attraction between air bubbles and the solids is predicted. On the other hand, quartz dehydrated at a temperature above 1000°C is readily floatable without any collector, yet the classical DLVO theory would predict repulsive van der Waals and electrostatic forces between the two. It is clear that the additional force can be either attractive or repulsive, depending on the hydrophobic or hydrophilic nature of the solid surfaces.

Thanks to a recent breakthrough in measuring surface forces directly, the presence of additional long range attractive forces between hydrophobic surfaces and short range repulsive forces between strongly hydrated surfaces has been confirmed. The former has contributed significantly to comprehending the thin film rupture phenomena which occur in most flotation systems. The force between an air bubble and a solid surface has been directly measured with an atomic force microscope and results, shown in **Figure 7**, confirm the existence of additional attractive forces. It should be noted that the direct force

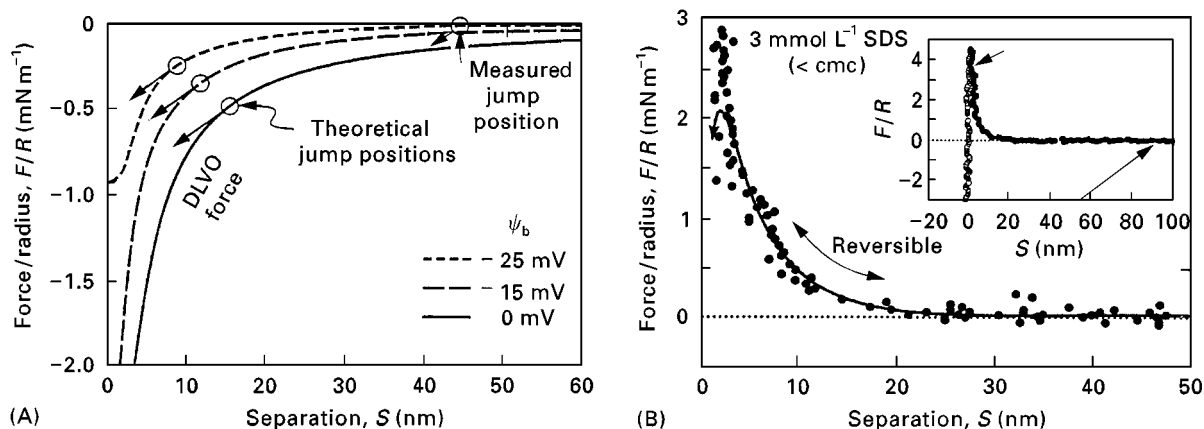

Figure 7 Forces between an air bubble and a silica particle in (A) an electrolyte solution with (B) added surfactant, measured directly with an atomic force microscope. A much greater jump in distance than predicted from the classical DLVO theory (A: shown by arrows) confirms the existence of additional attractive forces. In contrast, the presence of 3 mmol L^{-1} SDS changed the forces from a long range attraction to a long range repulsion, well-described by the DLVO theory (B), manifesting the role of surfactant in flotation.

measurement between an air bubble and a hydrophobic solid surface remains an unresolved challenge, even though it is most relevant to flotation.

Following recent advances in scientific instrumentation, such as the atomic force microscope, film balance and surface forces apparatus, flotation research has gone through a period of thermodynamic analysis of bubble-particle attachment to the understanding of intermolecular forces involved. These advances have allowed flotation subprocesses to be analysed from first principles. Bubble-particle adhesion, and hence flotation, for example requires particle-bubble contact (sliding) time greater than film rupture (induction) time controlled by wetting kinetics. An attempt has been made to derive a flotation rate equation from first principles by considering both surface forces and system hydrodynamics. The practical application of the derived equation in flotation process development remains to be explored. The empirical relations, outlined in a review by Radoev and Alexandrova (1992), remain the main source for process design and simulation.

It is important to note that chemistry, physics and mechanics, which form the three foundations of a flotation system and determine the process dynamics, are interrelated among themselves. This is emphasized in Figure 1 by a triangular relation on the base of the tetrahedron. Bubble size in a flotation system, for example, is determined by chemistry (addition of frother) which affects the physics of film stability (surface forces) balanced by mechanical forces and liquid viscosity. Only when these three factors are considered simultaneously can the flotation dynamics be optimized. An important area in flotation development is the innovations in: (i) on-stream analysis

(X-ray fluorescence analyser, ash analyser, nuclear magnetic resonance and image analysis); (ii) sensors (redox, ion-selective Eh and conductivity probes); (iii) dynamic process modelling (expert systems and artificial neural networks to mimic control actions by human operators); (iv) control (fuzzy logic and self-organizing controller); and (v) instrumentation. Details on these developments are not included in this article, and interested readers are referred to the recent review articles by Sastry and Fuerstenau (1988), Mavros and Matis (1991) and the *Proceedings of the XIX International Mineral Processing Congress* (1995).

Recent Advances in Flotation Practice

It appears unnecessary to list all of the minerals processed by flotation, since almost all minerals mined today can be separated effectively by froth flotation. In addition to developments in the three foundation areas of flotation (Figure 1), significant progress has also been made in circuit design. Following the introduction of reverse, bulk and differential flotation, the multifeed circuit, shown in Figure 8 and practised in China for processing copper sulfide, is considered to be one of the most recent advances in this regard. With the multifeed circuit, the improved recovery has been attributed largely to the autogenous carrier (piggyback) effect. The reduced reagent consumption, which creates a starving reagent addition, may have contributed to the improved concentrate grade (i.e. selectivity). In the Climax Mill (USA), the use of the multifeed circuit improved the molybdenite grade from 14 to 34% MoS_2 at comparable molybdenite recovery and

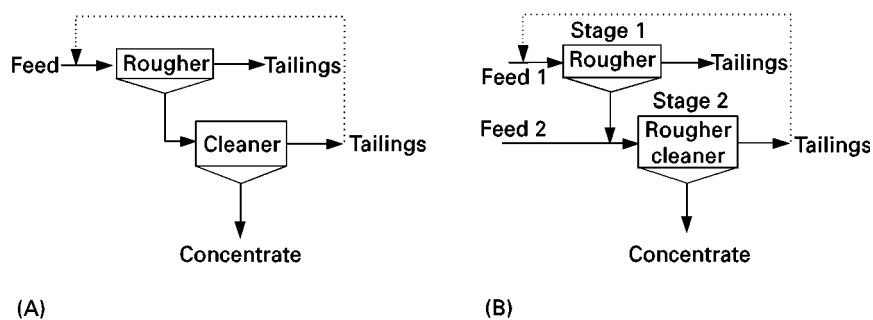

Figure 8 Comparison of (A) conventional rougher-cleaner circuit with (B) multifeed circuit. The dotted lines represent a variation of the circuits with recirculating loads. An added advantage with a multifeed circuit includes improved concentrate grade at reduced reagent consumption while maintaining the valuable recoveries.

reduced by half collector and frother consumptions. Another recent development is flash flotation which uses a coarse flotation cell (Skim-Air) in a grinding circuit to produce final concentrate from a cyclone underflow stream before further grinding (Figure 9). This approach minimizes overgrinding of valuable material richer in the cyclone underflow than in the feed stream. In addition to increased recovery, an improved throughput for the subsequent unit operations and the high dewatering efficiency of final concentrate are recognized with flash flotation. In tackling the challenge of fine particle flotation, high intensity conditioning has been developed. The improved process performance has been attributed to mechanical surface cleaning of slimes, shear-induced aggregation of target particles and, yet to be confirmed, *in situ* bubble formation on hydrophobized particles by hydrodynamic cavitation and resultant bubble-particle aggregation. Online pulp potential

control assisted by nitrogen as the carrier gas has also been engineered in flotation machines and columns as a means of improving selectivity of sulfide mineral separation.

Concluding Remarks

With generations of research efforts, flotation has matured into a process of choice for many separation tasks, including mineral separation, bitumen extraction from tar sands, soil remediation, materials recycling, de-inking, de-oiling, de-colouring, biological species fractionation and industrial effluent detoxification in the form of either froth flotation or absorptive bubble separation. Both inventions and innovations have played an indispensable role in flotation development in an evolutionary, rather than a revolutionary, fashion. Although flotation practice has always been ahead of flotation science, the gaps

Figure 9 Schematics of a flash flotation circuit with a coarse flotation before grinding. The circuit minimizes overgrinding of valuables and improves the recovery and product quality at an increased throughput.

between the two have narrowed significantly. Improving fundamental understanding of the flotation process remains the main focus of research for the future. The areas where significant advances are anticipated include: (i) design and synthesis of more effective, environmentally friendly flotation reagents (mainly collectors, frothers and depressants); (ii) engineering of a pulp potential monitor (mineral electrodes) and control in sulfide flotation practice; (iii) development of new flotation cells to maximize separation efficiency and minimize energy consumption; (iv) understanding and utilization of biotreatment to replace both collectors and depressants; and (v) design of a better and reliable process control system based on further development of sensors and simulators. The main challenge that flotation engineers and scientists are facing is to develop viable process alternatives for fine particle flotation. Four areas of immediate interests are: (i) the development and understanding of high intensity conditioning; (ii) hydrodynamic cavitation in flotation machines; (iii) selective aggregation by coagulation, flocculation or oil agglomeration; and (iv) practical conditions for collectorless flotation of sulfide ores.

Further research is needed in the area of flotation chemistry and implementation of the outcome into process development. All of these are driven by the depletion of rich and simple mineral resources, reduction of metal prices and the increase of environmental pressures. The processing of tailings with a gravity concentrator at Laurium, from 1864 to 1920, left tailings containing 3% lead, these were reprocessed again in 1955 by flotation with a resulting tailings assay of 0.3% lead. It is not unrealistic to suggest that

the resultant tailings may be reprocessed in the future with further innovative developments, such as integration of biotreatment in flotation. To conclude, there is a long-awaited need to widen the range of flotation applications to nonmineral-processing applications, such as in material recycling and waste remediation, with revolutionary changes in flotation technology.

Hydrophobic Surface State Flotation

J. D. Miller, University of Utah, Salt Lake City, UT, USA

Introduction

The essence of particle separation by flotation is the creation of a hydrophobic surface state, i.e. a surface that is not wetted by water, a particle surface at which bubble attachment will occur leading to flotation due to the buoyancy of the particle-bubble aggregate. (Particle flotation can also, however, be accomplished by bubble entrapment rather than by bubble attachment. For example, entrapment of air during particle aggregation/flocculation can lead to the flotation of aeroflocs.) In many instances this hydrophobicity must be

established in a selective manner, frequently by collector (surfactant) addition, so that one particle type can be separated from other particle types which are maintained in a hydrophilic state.

The extent to which a surface is hydrophobic can be described in various ways. Two of the most common laboratory methods are contact-angle measurement and bubble attachment time measurement. The contact angle measurement tends to be an equilibrium, or pseudo-equilibrium, measure of hydrophobicity, while the bubble attachment time measurement is a kinetic measure of hydrophobicity. Other measures of hydrophobicity are also possible and include bubble pick-up and microflotation experiments.

Figure 1 Bubble attachment. Sequence of events.

Bubble Attachment

Bubble attachment at a hydrophobic surface occurs due to the instability of the aqueous film that separates the bubble from the surface. As the bubble approaches the surface, to such a separation distance that the bubble may be distorted, there is a thinning of the aqueous film to the point at which rupture occurs. This time of film thinning is called the 'induction time'. After rupture, the film is displaced as it recedes across the hydrophobic surface to establish the equilibrium contact angle. The total time of film thinning and film displacement is the bubble attachment time. The sequence of events at a polished surface is depicted in **Figure 1**, where the bubble attachment time is shown to consist of the film thinning (induction) time and the film displacement time. Thus the bubble attachment time is, in part, a measure of hydrophobicity and can vary from less than a millisecond to several seconds in magnitude. Although the hydrophobicity should be an intrinsic property of the system, the bubble attachment time measurement is significantly influenced by the experimental method. For example, the bubble attachment time for a sample of naturally hydrophobic bituminous coal was found to vary by a factor of more than 50 when the results obtained for a polished surface are compared with those obtained for a particle bed as revealed in **Table 1**. Similar results have been re-

ported for chalcopyrite. The very strong effect of contact area, hydrodynamics, and surface morphology are revealed from these data. For a given experimental technique, the shorter the bubble attachment time, the greater the hydrophobicity.

Contact Angle

The equilibrium state for the attached bubble is described by the contact angle, θ , as indicated in **Figure 2**. The contact angle for this three-phase equilibrium is related to the respective interfacial tensions by Young's equation,

$$\gamma_{SG} = \gamma_{SL} + \gamma_{LG} \cos \theta$$

The attachment process should be spontaneous for all finite contact angles, but generally a contact angle of at least 20° is required for bubble attachment and flotation. The greater the contact angle, the greater the hydrophobicity. Of course contact angles much greater than 20° are desired in order to make effective flotation separations. Generally the characteristic contact angles for flotation systems rarely exceed 100° . Typical values for naturally hydrophobic minerals are given in **Table 2**. Larger contact angles are

Table 1 Measured bubble attachment times for a low-volatile bituminous coal at a polished surface and at a bed of particles (100×200 mesh)

Mode of attachment	Gas phase	Attachment time (ms)
Polished surface	Air	180–200
	N ₂	170–190
	CO ₂	140–150
Particle bed	Air	3
	N ₂	–
	CO ₂	3

Pyrophyllite	Al ₂ (Si ₄ O ₁₀)(OH) ₂	001	
Talc	Mg ₃ (Si ₄ O ₁₀)(OH) ₂	001	88
Iodyrite	AgI		20

possible for specially prepared surfaces which are highly water repellant. For example, water contact angles exceeding 150° have been observed for specially prepared surfaces as shown in Figure 3.

Nonpolar Surfaces

It is evident that the hydrophobic surface state is established by nonpolar surfaces which are not extensively hydrated. Now the nonpolar surface criterion for hydrophobicity is well known and has been established for some time. Such characteristics of the hydrophobic surface state have been known since the mid-1950s. In some cases the hydrophobic surface state is due to the elemental composition of the surface; the surface is composed of elements of low polarity that do not hydrogen bond with water molecules. These elements include C, H, S, and large atoms of low polarizability. Examples include graph-

ite, coal, elemental sulfur, and iodyrite. Even the surfaces of metal sulfide minerals are reported to be hydrophobic in the absence of oxygen and can be considered to be intrinsically hydrophobic. Of course, exposure to even parts per billion of oxygen can lead to oxygen fixation and subsequent complex electrochemical reactions, the surface products of which may or may not be hydrophilic depending on solution chemistry and the extent of oxidation. In general, simply the fixation of oxygen at sulfide mineral surfaces can provide sufficient surface polarity to create a hydrophilic state. Nevertheless, under anaerobic conditions the sulfide surface is expected to be hydrophobic due to its limited ability to hydrogen bond with interfacial water molecules.

In addition to the elemental composition of the surface, the crystal structure and bonding influence the polarity of mineral surfaces. In some cases, specifically surfaces that are created by breakage of weak van der Waals bonds, a nonpolar surface is created even containing elements that normally would hydrogen bond and be hydrated by interfacial water molecules. Examples include pyrophyllite, talc, and boric acid. In this way it has been established that the hydrophobic nonpolar surface state can arise from the intrinsic properties of the elements of which the surface is composed and from bonding considerations associated with the crystal structure. Finally it should be noted that hydrophobic surfaces can be charged just as hydrophilic surfaces are and that generally maximum hydrophobicity is found at the isoelectric point, or the point of zero charge, of the surface.

**Figure 3** Water contact angle for a sessile drop of water at the surface of a newly developed water repellant material.

Water Film Stability

Of course the hydrophobic surface state must not only be described in terms of the elemental surface composition and structure but also must be described in terms of the interfacial water structure; in fact the instability of the interfacial water film accounts for bubble attachment at a hydrophobic surface. The characteristic features of interfacial water and its instability at a hydrophobic surface have not been so well described until recently. Now with the use of atomic force microscopy, surface spectroscopy, and a laser optical cavity technique, these features of interfacial water have been revealed in greater detail.

Direct force measurements during the 1980s and 1990s have revealed that attractive hydrophobic forces are usually 10 to 100 times larger than those expected from van der Waals interactions. These forces extend to distances of as much as 100–200 nm from the surface. The extent of attraction between hydrophobic surfaces is related to the degree of hydrophobicity but seems to be also independently effected by discrete features of the surface like roughness and heterogeneity.

At the same time, during the 1990s, *in situ* surface spectroscopy (sum frequency generation (SFG) and Fourier transform infrared/internal reflection spectroscopy (FTIR/IRS)) of water at hydrophobic surfaces has revealed important characteristics of interfacial water. The SFG spectral information clearly shows a distinction between water at a hydrophobic surface and water at a hydrophilic surface. Interfacial water at a hydrophobic surface is distinguished by a stronger absorption band at 3600 cm^{-1} characteristic of a dangling free OH bond. In contrast, interfacial water at a hydrophilic surface is distinguished by a diminished absorption band at 3600 cm^{-1} and a stronger signal at 3200 cm^{-1} characteristic of an ice-like structure with complete tetrahedral coordination. Based on these surface spectroscopy studies, it appears that interfacial water at a hydrophilic surface can be viewed as organized dipoles in tetrahedral coordination and oriented with respect to the polarity of the hydrophilic surface, whereas interfacial water mol-

ecules at a hydrophobic surface are not so well organized at the surface and have incomplete tetrahedral coordination with dangling free OH bonds.

It might be assumed that this *in situ* spectral data can then be used to account for film instability at a hydrophobic surface. Unfortunately, it seems that the phenomenon is not that simple. It is expected that the interfacial water structure will extend only a distance of a few molecular diameters, not more than a few nanometers or so. On the other hand, the hydrophobic attractive forces can extend to 100 nm, and even more. Thus it would seem that film instability at a hydrophobic surface involves more than just the hydrogen bonding characteristics of interfacial water.

Some researchers have attributed film instability to cavitation phenomena. The presence of nanobubbles or defects in the interfacial water region at a hydrophobic surface has been reported based on experimental results using a laser optical cavity technique. Also it should be noted that surface force measurements reveal that the range of the attractive hydrophobic force is significantly greater in gas-saturated solution than in degassed solution. It is expected that slight perturbations in the pressure field would cause these nanobubbles to coalesce and form cavities which upon further coalescence would lead to cavitation and failure of the water film at a hydrophobic surface as shown in Figure 4. In some cases, discontinuities during force measurements were observed which may be attributed to the phase transition (cavity formation) between approaching surfaces. Finally, recent FTIR/IRS spectroscopic evidence, indeed, shows that dissolved gas is accommodated at a hydrophobic surface but not so at a hydrophilic surface. Thus the presence of nanobubbles in the interfacial water region of a hydrophobic surface is supported by these spectroscopic results.

Summary

In summary, the hydrophobic surface state must be considered both with regard to the particle surface and with regard to the adjacent interfacial water

Figure 4 Schematic picture of cavitation phenomena during approach of hydrophobic sphere and hydrophobic plane in water. (A) Layers of lower medium density (adsorbed gas molecules), (B) nanobubbles formation, (C) bridging cavity formation, and (D) multiple bridging cavities, leading to film rupture and attachment.

region. The particle surface must be of low polarity which is determined by elemental composition and/or structural bonding considerations. Water film instability at a hydrophobic surface arises not only from a disrupted interfacial water structure but also from a cavitation phenomenon which involves coalescence of nanobubbles in the interfacial water region. Such is the nature of the hydrophobic surface state.

Intensive Cells: Design

G. J. Jameson, University of Newcastle, Callaghan, NSW, Australia

Introduction

In conventional flotation practice, the particles to be treated are dispersed in a suspension in water. Reagents are added to make the particles to be floated hydrophobic or nonwetting. The particles which are to be left behind remain in a wettable state. Air bubbles are then introduced into the slurry or pulp in a contacting device or cell, and collide with the non-wetted particles, carrying them to the surface where

they form a froth. The froth concentrate flows over a weir and out of the flotation cell, while the unwanted tailings flow out of the bottom.

The effectiveness of this type of cell lies in the ability of the bubbles rising in the liquid to collide with particles in suspension. Because the concentration or hold-up of air in the liquid is not very high – typically less than 10% by volume – the probability of a collision is correspondingly low. The low frequency of useful collisions between an individual bubble and the particles in a flotation machine can be overcome by increasing the residence time of the suspension. In this way, by using long residence times which can sometimes be as much as an hour in a

flotation bank, it is possible to achieve high recoveries of a floatable material.

In recent times, a number of flotation machines have been introduced which seek to reduce the residence time, by using new ways to bring about the contact between particles and bubbles. These are referred to as intensive flotation cells. Although the way in which the air is introduced – and the bubbles are made – differs from one type to another, they share a common feature. The collision between particles and bubbles does not take place within a liquid with a low number concentration of bubbles, or with a low gas hold-up. Rather, the air is introduced in such a way that contact is made in a device with a high air void fraction – a high ratio of gas volume to a given liquid volume. Once contact has been made, the bubbly mixture, which resembles a dense foam, passes to another vessel where the bubbles can disengage from the liquid, bearing their load of floatable particles to the supernatant froth layer.

The formation of bonds between bubbles and particles after collision is an essential step in flotation, and the topic has received much attention in flotation theory and practice. It has not always been appreciated that phenomena which take place in the froth phase above the liquid can also have a large effect on overall flotation performance. While the yield or recovery of floatable material obviously requires an efficient mechanism for contacting particles and bubbles, the grade or purity of the product is largely determined by froth-phase phenomena. When a continuous cloud of bubbles, whose surface contains selectively adsorbed hydrophobic particles, rises upwards through the froth-liquid interface, some of the liquid is trapped between the bubbles and is entrained into the froth layer. This liquid is the same composition as the main liquid in the flotation cell, so the concentration of gangue or waste particles in the liquid in the froth is approximately the same as in the liquid layer from which it arose, at least in the first instance. The presence of nonselective particles in the entrained water will reduce the grade of the concentrate product. While the bubbles are rising in the froth, the liquid layers between bubbles are draining, and gangue particles are carried downward, returning to the pulp layer. Over the last 20 years, it has become commonplace to apply clean water to the top of the froth layer, causing a continuous downward flow through the froth which tends to wash out the entrained gangue. With froth washing, flotation products of very high grade can easily be produced. (This assumes that the valuable material is completely liberated from the gangue by grinding. Any gangue which is locked into valuables

will generally float with the latter, thereby reducing the concentrate grade.)

The main objectives in the design of froth flotation equipment are always the same: to produce a device capable of achieving high grades and recoveries, with small size, minimum capital and operating costs, ease of operation and maintenance. To meet these objectives, many new cells have been tried over the years. This review will concentrate on the limited range of such cells which can genuinely be described as intensive, in that the contact time between bubbles and particles is very short, and the flotation cells are correspondingly quite small relative to the throughput. These are the air-sparged hydrocyclone (ASH), the Jameson cell, and the Ekof cell.

The Air-Sparged Hydrocyclone

The ASH was invented by Professor Jan Miller of the University of Utah, and was patented in the USA in 1981. It makes use of the centrifugal forces which arise when air is sparged through the walls of a hydrocyclone. The device consists of a cylinder with a porous wall enclosed in an external chamber (**Figure 1**). The feed slurry enters tangentially through a conventional hydrocyclone header at the top of the cyclone, to form an annular liquid layer on the inner surface of the porous wall. The slurry moves downwards through the cylinder with a strong swirling motion. Bubbles are generated at the surface of the porous wall and, because of the swirling motion, bubbles which are produced on the porous surface experience an inwardly directed centrifugal force which carries them away from the wall, to pass quickly through the annular layer, collecting floatable particles on the way, forming a froth layer in the core of the cyclone. The froth leaves through the vortex finder in the top of the cylinder, while the tailing particles whose density is greater than that of water move towards the wall and are discharged through an annular gap in the bottom of the vessel.

An important feature of the ASH is the froth pedestal in the base. This stabilizes the froth and prevents it from passing out in the tailings. The froth zone is forced to move upwards through the vortex finder, carrying the hydrophobic particles. The hydrophilic particles are carried out in the tailings slurry.

The performance of the ASH is dictated by the fluid motion in the swirl layer adjacent to the porous wall, which in turn is controlled by the kinetic energy in the inflowing slurry, and the physical dimensions of the header and the vertical cylinder.

The bubble contact time in the hydrocyclone is of the same order as that of the pulp residence time, around 10 s. There is a correspondingly high capacity

Figure 1 Schematic of the air-sparged hydrocyclone.

per unit volume, which is of the order of 100–600 tons day⁻¹ ft⁻³ of cell volume (3600–21 500 tonne day⁻¹ m⁻³) as against 1–2 tons day ft⁻³ (35–70 tonnes day⁻¹ m⁻³) for mechanical cells and columns. To date, the cells are not very large, but the capacity is quite high. Thus an ASH of diameter 5 cm and height 50 cm has a capacity of 3–18 tpd of solids.

The feed enters at conventional hydrocyclone pressures of 5–25 psi (35–170 kPa) and the air is supplied at a relatively high pressure of around 65 psi (440 kPa), which is necessary to force the air through the porous wall at the required flow rate.

An important parameter which limits the performance of flotation cells is the superficial velocity J_g , which is the volumetric flow rate of the flotation air divided by the cross-sectional area of the pulp normal to the direction of the air flow. A high J_g will lead to a high concentrate production rate, other things being equal. In conventional cells, the only force acting on the liquid in the froth is that of gravity. Because of the centrifugal field in the ASH, the drainage force on the liquid in the froth is enhanced, and high J_g s are possible. Thus, the typical air velocity in an ASH is around 1 standard L min⁻¹ cm⁻² of cylinder wall, which corresponds to a superficial velocity J_g of 17 cm s⁻¹. This figure may be compared with typical values for flotation columns, which are of the order of

0.5–4 cm s⁻¹, and mechanical cells where the figure is generally lower still – around 1 cm s⁻¹. The consequence is that the ratio of air-to-pulp flow rates can be very high, leading to high recoveries despite the short residence time. Reported values of the air-to-pulp ratio are as high as 16 : 1. In mechanical cells and flotation columns, the ratio is usually 1 : 1.

As far as contact between particles and bubbles is concerned, the ASH is clearly a very intensive flotation device. However, it is not so effective at handling the froth-phase requirements. Ideally, to obtain high grades, it is necessary to be able to apply clean washwater, which can drain through the froth and flush the gangue into the tailings stream, while leaving the hydrophobic material attached to the bubbles. For this to occur, the velocity at which water can drain through the froth under gravity must be greater than the superficial upward froth velocity in the core. Using published data, it is possible to calculate that the axial upward velocity of the froth core in an ASH is in the range 180–1300 cm s⁻¹. The diameter of flotation columns is fixed to allow for froth washing and the maximum working superficial air velocity J_g is about 4 cm s⁻¹ – far below the values attained in the ASH. Evidently it is not possible to design an ASH which can allow both intensive contact between bubbles and particles, and effective control of the

froth to obtain high grades. Accordingly, the ASH is most effective in applications where grade is unimportant, and where high recovery is desired. It is not surprising that the first large scale applications have appeared in the paper industry, for the removal of toner particles from recycled paper.

The Jameson Cell

The Jameson flotation cell was invented by Professor Graeme Jameson at the University of Newcastle, Australia, in 1986. It was developed to a practical reality at Mount Isa Mines, Mount Isa, Queensland, and was licensed to MIM Holdings of Brisbane in 1989. To date, there are 187 installations worldwide, in 19 countries. The cell is used for roughing, scavenging and cleaning, and also for removing oil haze from solvent extraction liquors. The distribution by field of use is coal 37%; copper 29%; other minerals 17%; and solvent extraction 17%.

In this cell, contact between particles and bubbles takes place in a dense foam which is produced in a vertical downcomer, as depicted in Figure 2. The pulp is introduced to the top of the downcomer as a confined liquid jet, and air is entrained into the feed and broken up into fine bubbles by the jet. A dense foam with a high void fraction is created in the

downcomer, creating a very favourable environment for collision of particles and bubbles. In fact, because of the high void fraction, of the order 50–60% by volume, the pulp is distributed in the form of thin liquid films between the bubbles, and collection occurs by migration of particles within the thin films, which are not much thicker than the diameter of the particles.

The dense mixture of bubbles and pulp discharges at the base of the downcomer, and the bubbles disengage from the pulp, rising into the froth layer. The bubble-free pulp discharges as tailings from the bottom of the cell. The froth behaves like that on top of a flotation column, in that grade and recovery can be strongly influenced by the froth depth and the application of washwater, and the upward superficial air velocity J_g . From the point of view of collection, the downcomer operates best when the ratio of air rate to feed rate is less than one-to-one on a volume basis.

The froth is treated much as in conventional columns. Washwater is usually applied if a high grade product is required. As with columns, when the air rate is altered, both steps in the flotation process – particle/bubble contact and froth entrainment – are affected. Thus an increase in air rate may cause an increase in recovery because more bubble surface area is created on which to capture particles, and because changes in the ratio of bubble to particle sizes will affect the probability of collision. At the same time, there may be an increase in entrainment of the gangue into the froth which may lead to a decrease in grade, unless steps are taken to remove the entrained gangue by changes in froth depth and washwater rate. Thus the optimum performance of the cell is related to the air superficial velocity, J_g .

The key features of the cell are:

1. The contacting environment is highly intensive, so that only short residence times are required. The total cell residence time is 1–2 min; the residence time in the downcomer is around 10 s. A short column is therefore produced which is ideal for retrofit, or installation in cramped headroom. The floor area is, however, similar to that required by conventional columns for the same throughput.
2. The bubbles formed by the impinging jet are very small, offering enhanced carrying capabilities for fine concentrate particles.
3. Air is drawn in from the atmosphere and no air compressor or blower is needed.
4. In the cleaning zone, with the use of washwater, the levels of concentrate grade approach the maximum levels possible.

Figure 2 Schematic of the Jameson cell. The height overall is approximately 2–3 m. The cross-sectional area of the cell is directly proportional to the desired feed flow rate.

The size of bubbles produced in the flotation cell is an important determinant of cell capacity. The mass of particles which can be carried out on the surface of the bubbles is dependent on the gas-liquid interfacial area. For a given gas flow rate, the interfacial area is inversely proportional to the bubble size, so there is an advantage in making small bubbles. However, it must be kept in mind that in the disengagement zone, the buoyancy of the bubbles must be sufficient to lift particles of the largest size in the pulp to the surface of the liquid. The best compromise appears to be to make bubbles in the range 0.35–1 mm. Bubble sizings on full scale operating cells and test cells show that the Jameson cell produces an arithmetic mean bubble diameter of the order of 300–600 μm , while the Sauter (volume-to-surface) mean diameter, d_{vs} , is of the order 360–950 μm . These sizings compare very favourably with conventional columns where the Sauter mean bubble size is typically 2–3 mm.

Some general operating characteristics of the Jameson cell are now discussed.

Air Velocity in the Cell

The superficial gas velocity is the upward superficial velocity of air in a flotation cell, calculated by dividing the downcomer air rate ($\text{cm}^3 \text{s}^{-1}$) by the cross-sectional area (cm^2) of the riser part of the cell. The cell is normally circular or rectangular in section, and the appropriate cross-sectional area is simply the area normal to the direction of the flow of the froth, excluding the area occupied by the downcomer(s). The superficial velocity J_g is conveniently expressed in units of cm s^{-1} because values typically range from 0.5 to 4 cm s^{-1} in practice.

The recovery and concentrate carrying rate ($\text{g min}^{-1} \text{cm}^{-2}$) tend to increase with increasing J_g . As in conventional columns, there is a limiting upward flux of bubble surface through the pulp above which froth flooding occurs, resulting in the loss of froth-pulp interface, a very wet froth and total loss of selectivity. There is consequently a maximum air rate $J_{g\text{max}}$ defined by this limiting flux and bubble size. In flooding, the entire cell fills with froth as the only stable phase, and there is no pulp phase.

The operating J_g used in the sizing of the Jameson cell depends strongly on the application, and on the residual reagent concentrations from any upstream processes. Generally speaking, low values ($J_g = 0.4\text{--}0.8 \text{ cm s}^{-1}$) are employed in cleaning applications, and high values ($J_g = 1.0\text{--}2.0 \text{ cm s}^{-1}$) are employed in roughing or scavenging applications.

In cleaning operations, a high proportion of the feed reports to the concentrate, and the froth loading tends to be high. Consequently, the bubbles are well

coated with particles, which tend to stabilize the froth by reducing the froth coalescence rate. The drainage rate of the interstitial liquid in the froth is retarded by the relatively high concentration of particles, which has the effect of increasing the apparent viscosity of the interstitial liquid. Accordingly, it is necessary to design for lower values of J_g to allow time for the gangue to drain from the froth to obtain the required high grade. In roughing applications, however, only a small fraction of the feed reports to the concentrate and the froths formed tend to be less stable as a consequence. Also, gangue entrainment is not such a serious problem, because it can be dealt with in the downstream cleaning circuit. As a consequence of the higher coalescence rate the froth bed is shallower than that of the cleaners and a lower froth residence time will give good drainage. It is therefore usual to design a Jameson cell for a roughing application with a higher J_g than in the cleaners.

In some circumstances, high residual concentration of reagents in the feed necessitates the use of low values of J_g to avoid froth flooding. Although frother concentration is of primary importance to bubble size and hence the advent of froth flooding, circumstances have arisen where collector and frother interaction has been observed. In such a case, the frother dose should be decreased if collector dose is increased, and vice versa. Too high a frother or collector concentration can lead to froth flooding while too low a dose can lead to loss of froth stability.

Particle size can also have an influence on the maximum J_g , due to its effect on froth stability through bubble-bridging. Small particles (less than 100 μm) are easily collected at low gas rates, while recovery of coarser particles may be assisted by higher rates.

A complex system of liquid and air recirculation patterns forms in the bottom of the cell. The cell design is based on downcomer flows and downcomer placement to optimize this system to produce best grade and recovery. There is no limit on cell volume, providing the net downwards velocity of pulp, J_L , is sufficiently low to avoid the entrainment of bubbles in the underflow. When the froth and disengagement zones have the same cross-sectional area, the two important velocities are the rate of rise of the bubbles in the pulp, and the rate of drainage of liquid in the froth. The former is usually greater than the latter, so that a column sized to give the correct J_g will also give the correct J_L , and bubble entrainment in the downward flow will not be a problem.

Froth Depth

The froth phase in a Jameson cell can be controlled as in conventional columns. Shallow froth depths (less

than 200 mm) are used where high recovery is necessary and grade is of secondary importance, while deeper froths (up to 1 m) are employed to obtain maximum concentrate grade. Shallow froths result in significant entrainment of very fine ($< 10 \mu\text{m}$) gangue mineral which accompany the pulp phase. With deeper froths, significant drainage of hydrophilic gangue will take place, producing a higher grade concentrate, and a higher percentage of solids in the concentrate. Under some circumstances, the addition of washwater to the froth will assist froth mobility, and assist an otherwise immobile froth to keep moving to the overflow lip.

Air/Pulp Ratio

The air-to-pulp ratio (the ratio of the volumetric flow rates of air and pulp) in Jameson cells is usually in the range 0.3–0.9. Experiences with large (2–3 m diameter) Jameson cells indicate that operation at a low air/pulp ratio does not detract from metallurgical performance providing the superficial gas velocity J_g is maintained above 0.4 cm s^{-1} . Operation at lower air/pulp ratios has a stabilizing effect producing a finer, more uniform bubble size. A significant advantage of operation at lower air/feed ratios is that lower concentrations of frother are required.

The flux of interfacial area for a given gas rate varies directly as the gas flow rate and inversely as the bubble size. Thus the flux of bubble surface area, interfacial area per unit area of column cross-section per unit time, can be maintained with reduced superficial gas rate, providing the bubble size decreases accordingly.

The Effect of Washwater

Clean water can be applied to the top of the froth, to flush entrained material downwards, preventing it from flowing out with the flotation product. There are two measures which are used to measure and control washwater addition: the bias and the washwater ratio.

Bias is the absolute excess of the washwater applied to the froth, over the quantity of water being recovered in the concentrate, expressed as a superficial velocity J_b (cm s^{-1}): $J_b = (Q_{\text{ww}} - Q_{\text{wc}})/A_c$, where Q_{ww} , Q_{wc} are the volumetric flow rates of washwater and water in concentrate, and A_c is the cross-sectional area of the column.

The washwater ratio is defined as the ratio of the washwater addition rate, to the flow rate of water in the concentrate: $W = Q_{\text{ww}}/Q_{\text{wc}}$. The washwater ratio is a relative measure of the amount of washwater applied. If no washwater is used, the washwater ratio is zero and the bias is negative. When $J_b = 0$, $W = 1$.

A positive bias corresponds to washwater ratios greater than unity.

Although the bias does give an indication of the absolute amount of washwater being added, its use can be misleading because it does not take into account the wide variation in the absolute values of the rate of water entrainment in the concentrate. It is preferable to use the washwater ratio, which is a relative figure. In practice, it has been found that best performance is achieved when the washwater ratio is greater than 1.

Scale-Up

Scale-up of the Jameson cell is relatively simple, since the flotation capacity is proportional to the cross-sectional area of the cell, and the flow capabilities of the downcomer. Downcomers range in size from 0.2 to 0.36 m, and a large installation will have multiple downcomers. Large cells are typically 5 m in diameter, with 12–16 downcomers, and handle flow rates of $1200 \text{ m}^3 \text{ h}^{-1}$. Extensive testing has shown that the results obtained in small test units, of diameter 0.3 m, give an accurate picture of the performance of a large cell on the same feed. In many cases, test work is not required, because of the availability of data from operational plants which will allow a design to be established for a new application with an ore of similar characteristics.

Because there is a limit on the amount of air which can be supplied to a given amount of feed slurry in the downcomer, the Jameson cell can become limited by carrying capacity. Thus, if there is an excess of particles in the feed above the mass which can be carried by the available surface area of bubbles, some of the hydrophobic material will not be transferred to the concentrate. In such cases, it may be necessary to install a second cell in series with the first, to ensure a high recovery of the values. An alternative which is increasingly being used is to recycle part of the tailings. The feed pump is then sized so as to be well above the normal operating capacity. The feed pump draws from a pump box in the circuit ahead of the Jameson cell, and receives flow from two sources: new feed and recycled tails. It has been found that the recovery with recycle in the range 30–50% of the feed flow rate is equivalent to the addition of a second cell in series.

The Ekof Cell

The Ekof cell, also known as the Pneuflo cell is marketed by KHD Humboldt Wedag, of Bochum, Germany. It arose from a cell invented by Professor Albert Bahr, of Clausthal Technical University, Germany, in 1974. The Bahr cell consists of a vessel

of inverted conical form. The feed is premixed with air in a series of aerators distributed around the periphery of the vessel, in which air is injected through a porous wall into the transversely moving pulp. The bubbly pulp mixture is then fed to the vessel, where the bubbles rise and make contact with the floatable particles and carry them to the surface.

In the Bahr cell, the air-pulp mixture is introduced through pipes which enter through the wall of the vessel part-way up from the bottom of the cone, pointing vertically upwards to form a jet or plume. The jets are equispaced about the periphery of the cell. The idea was that a jet would spread out and mix with the pulp in the tank, bringing the bubbles into contact with the particles. Each jet would increase in area with vertical height, until at the surface the cross-sectional area of the jets would be about the same as that of the cell. The problem with this concept is that, as the size of the vessel and the design throughput increases, the height of the cell must increase as well. This difficulty was overcome in a later design in which the pipes delivering the air-pulp mixture are directed tangential to the cell wall, so that a low speed swirl develops. This design has been referred to as a Pneufлот cell. In both the Bahr and Pneufлот cells, the froth discharges over a lip into an annular launder which surrounds the vessel.

Because of the way the bubbles are generated, a high air pressure is needed to drive the air through the porous wall, and a relatively high feed pressure is needed to accelerate the pulp to the required speed in the aerator. In early models, froth washing was not provided, but it is available in later versions. The Bahr cell has had success especially in coal flotation.

In Pneufлот cells of the new form (Figure 3) the feed enters through a vertical pipe, and compressed air is introduced through small openings in an aerator unit at the top of the pipe. A model is also available in which the air is introduced into a Venturi. The aerated pulp is led through a central pipe to a low point in the flotation cell, and is diverted upwards by a distributor. The purpose of the distributor is to create an upward flow of bubbles which promotes flotation of coarse particles.

The latest form of Pneufлот cells is fitted with a froth crowder, which is of value when the loading of particles in the froth is low, and the froth is relatively unstable. The use of washwater is also possible in this design, as depicted in Figure 3.

Scale-up of the Pneufлот cell is not possible without testing on a pilot plant. There is no flotation time as in mechanical cells. The number of stages needed for a particular application can be determined by tests in which a Pneufлот cell is fed from an agitated tank at $6\text{--}10 \text{ m}^3 \text{ h}^{-1}$, with recycle of tailings from the cell

Figure 3 The essential features of the Ekof or Pneufлот cell of the new form.

back into the tank. From a plot of the concentration of the element of interest in the froth concentrate, the feed and the tailings, all as a function of time, it is possible to deduce the number of stages required by a stepping procedure.

The Pneufлот cell is in use in a number of applications, on magnesite, copper, galenafluorite, etc.

Future Developments

Further intensification of the flotation process is likely to come about in two directions. The processes of bubble contacting, bubble transfer to the pulp-liquid interface and froth drainage, are all responsive to a force field which can induce body forces on the liquid. In normal circumstances, the main body force is that of gravity. Accordingly, if the effective flotation rate per unit volume is to be increased, the logical step is to subject both the liquid and the froth to a centrifugal field. This will undoubtedly increase the mechanical complexity of the apparatus, and the saving in flotation cell volume may not warrant the extra cost of building, running and maintaining the equipment. Another possible direction for increased intensification is in the design of the initial gas-liquid contacting device. We have seen that, in both the Jameson cell and the Ekof cell, contacting takes place in a pipe or downcomer which must be of sufficient length to ensure efficient contact between bubbles and particles. It is likely that other

contactors could be devised which could bring about essentially instantaneous contact between particles and bubbles, effectively eliminating the downcomer. However, the over-riding objectives mentioned earlier – achieving high grades and recoveries, with small size, minimum capital and operating costs, in equipment which is easy to operate and maintain – will always remain the prime concerns of industrial users. In any new approaches, these objectives must be kept in view.

Oil and Water Separation

B. Knox-Holmes, Baker Hughes Process Systems, Rugby, UK

Development

The process of flotation needs a gas bubble to collide with, and attach to, an oil droplet; because of the hydrophobic nature of the oil droplet, a

stable gas–oil matrix is formed. The buoyancy of the oil droplet is increased by the attachment of the gas bubble, causing the oil droplet to rise rapidly through the water. Typically, one gas bubble will attach to one similar-sized oil droplet as described by Leech. As the bubbles in the froth phase burst, an oil layer is formed on the surface of the water. Oil and froth are then removed from the surface on an intermittent or continuous basis, depending on the mechanism used.

Flotation is a kinetic process. While a number of flotation models exist, Klimpel's first-order rate equation has been demonstrated to provide modelling flexibility, ease of physical interpretation and a good fit to the experimental data. The Klimpel model is written as:

$$R_0(t) = \left[1 - \left(1 - \frac{\exp(-kt)}{kt} \right) \right]$$

where $R_0(t)$ is the fractional recovery of oil at time t (s) and k is the characteristic first rate constant (s^{-1}). The key to flotation is the production of air or gas bubbles. The two major techniques are known as dissolved air flotation (DAF) and induced air flotation (IAF). IAF can be further subdivided into mechanically and hydraulically induced flotation.

Mechanically induced flotation has now been used for about 100 years to separate from a suspension in water, particles of valuable mineral from gangue. In the mining industry this process is known as beneficiation. It is now the main method of concentrating copper, molybdenum, iron, phosphate, lead and zinc ores. In the minerals industry the air is dispersed as bubbles, either through an impeller in subaeration cells or through spargers in flotation columns. These and other variants of the air addition to flotation pulps are classified as IAF. In the petroleum industry natural gas, carbon dioxide or nitrogen may be used as the flotation gas, hence the process is termed induced gas flotation or IGF. The use of these gases significantly reduces downstream corrosion problems and possible hydrocarbon degradation caused by the use of air.

Flotation techniques can remove dispersed, but not dissolved oil. As environmental legislation specifies both the limiting oil concentration and also the biological oxygen demand (BOD) in the discharged water, flotation is often the second stage of a three-stage effluent treatment process of gravity separation, flotation and biological treatment. As an example, British Petroleum's Grangemouth facility has achieved discharge concentrations of 2–3 mg L⁻¹ oil-in-water using gravity separation in American Petroleum Institute (API) separators, followed by IAF with a final biological treatment stage to remove dissolved BOD materials including ammonia, phenols and sulfides. Limits for oil-in-water discharges vary around the world, typically between 15 and 40 mg L⁻¹. A maximum BOD of 216 mg L⁻¹ daily, with a monthly average of 53 mg L⁻¹ is considered to be achievable via the application of the best available technology by the United States Environmental Protection Agency.

Process Techniques

Dissolved Air Flotation (DAF)

In this method compressed air or gas (nitrogen, carbon dioxide or methane) is dissolved into all or part, of a process liquid under pressure in a retention vessel. The gas-oil-water mixture is then sent to a flotation cell, where the pressure is reduced, causing bubbles to come out of solution. The bubbles then attach to and are possibly nucleated on the oil and suspended particles.

The solubility of a gas in water is proportional to its partial pressure and inversely proportional to the water temperature. Solubility may be characterized by Henry's law:

$$X_G = \frac{p}{H_G}$$

where X_G is the molecular fraction of the gaseous component in the liquid, p is the partial gas pressure and H_G is a constant. The release of gas following a reduction in pressure is proportional to:

$$\Delta X_G = \frac{1}{H_G}(p - p_{\text{amb}})$$

The Henry's law constants at 25°C for some gases used in DAF are given in **Table 1**.

Flotation efficiency depends on the gas used. The effectiveness of the various gases in terms of their bubble release increases in the following order: nitrogen, oxygen, natural gas (methane) and carbon dioxide. Solubility is also reduced as the dissolved solids content is increased. The amount of gas that can be dissolved ranges from 50% to 90% of its equilibrium solubility depending on the design of the pressurization system.

There are a number of ways of dissolving gas under pressure. The gas can be sparged into the liquid in a pressure vessel, liquid can be trickled over a packed bed or sprayed into an unpacked vessel, gas can be entrained with ejectors or gas can be injected into the suction side of the recycle pump.

Table 1 Henry's law constants at 25°C for various gases used in DAF

Gas	H (atm/mol fraction)
Nitrogen	9.08×10^4
Oxygen	4.38×10^4
Methane	4.13×10^4
Carbon dioxide	1.64×10^3

Full flow pressurization transfers gas to the whole feed flow at a relatively low pressure of between 30 and 40 psi. This technique is suitable when sufficient gas can be dissolved to effect flotation, and the passage of the whole flow through a centrifugal pump will not impair the subsequent flotation process through floc shearing.

Partial flow pressurization passes a proportion of the full flow through the pressurization system at 60–75 psi. This method reduces the size of the pressurization system, resulting in significant cost savings. This technique is suitable when sufficient gas can be dissolved to effect flotation, and passage of the partial flow through the pump will not impair flotation.

Recycle flow pressurization is used when a natural or chemically formed floc is to be separated from a wastewater. A portion of the clarified flotation effluent is recycled and used as the carrier of the dissolved gas. This latter technique is the most efficient and accounts for the majority of installations.

Figure 1 shows a flowsheet of a system operating with recycle flow, a flotation cell operating at atmospheric pressure, a pressurized retention vessel, feed and recycle pumps and a backpressure valve.

A level controller controls the flow into the pressurization vessel and excess gas may be vented. There is adequate residence time (typically 1–3 min) in the pressurization vessel for sufficient gas dissolution to take place (50–90% saturation). The pressurized liquid from the vessel is mixed with fresh feed, and is discharged through a back pressure valve to the flotation tank.

In the flotation tank, which may be circular or rectangular, the pressure is typically reduced to atmospheric pressure, and this reduction or let-down causes bubbles between 1 and 120 μm in diameter to come out of solution. Bubble size depends on the operation of the pressure let-down valve.

Gas bubbles may form by nucleation on an oil droplet or solid particle, or they may come out of solution and then attach to oil droplets and suspended solids by collision, or they may become trapped in a solid–chemical or oil droplet–chemical floc. Chemical usage is determined by the total chemistry of the system, and a series of bottle tests at site will be necessary to optimize performance.

Floated oil and suspended solids are removed by skimmers, while non-floatable settleings are removed from the bottom of the cell by a grit scraper. The efficiency of the removal process depends on the ratio of air to solids and/or oil in the water. Too little air and separation will not be achieved. Too much air and the additional turbulence may actually reduce separation performance by causing floc re-entrainment, resulting in a reduction in energy efficiency.

The DAF machine can be characterized by being a relatively quiescent, high retention time device (15–30 min), using small volumes of dissolved gas (35–180 L m^{-3} of throughput). Depending on gas type, dissolution pressure, stream temperature and suspended solids loading, DAF may achieve 80–95% removal of free and emulsified oil and suspended solids.

Induced Gas Flotation (IGF)

In the induced gas flotation (IGF) (or IAF) process, which resembles the design of a subaeration minerals flotation cell (see Figure 2), bubbles are induced mechanically.

IGF uses a star-shaped impeller to generate intense local turbulence. This results in subatmospheric pressures being generated in the region surrounding the impeller which causes gas to be induced from the gas space at the top of the compartment via gas inlet

Figure 1 Flow diagram for a dissolved air flotation system. Courtesy of Baker Process.

Figure 2 Transverse cross-section of mechanical induced gas flotation machine. Courtesy of Baker Process.

ducts. Impeller rotation also causes an upward circulation from the bottom of the vessel. The gas and liquid mix to form a relatively homogenous two-phase (gas-liquid) dispersion which leaves the impeller with a mainly tangential velocity. The impeller is shrouded by a perforated cylindrical disperser, which separates the intensely turbulent inner zone from the relatively quiescent outer region of the rest of the cell. The dispersion passes through the disperser, which, because of the shear resistance to the flow through its wall, reduces the size of the bubbles and improves the uniformity of their radial distribution through the main cell volume, thereby increasing the probability of a bubble-droplet collision. After attachment of the bubble to the droplet or suspended particle, separation of oil and solids occurs by flotation. The surface of the cell remains relatively quiescent as a result of the baffling effect of the disperser and hood, which minimize re-entrainment of floated oil and solids. Since the upward surface flow is uniform in the outer quiescent region surrounding the impeller, the loaded bubbles which form a froth layer at the upper surface of the cell are usually removed simultaneously from both sides of the cell.

A reduction in bubble size reduces gas flow requirements because of the more favourable surface area-to-volume ratio of the smaller bubbles. There is, however, an optimum bubble size of about $10\ \mu\text{m}$ as the collision efficiency is reduced below this size. Design considerations require a balance between impeller power input and hence total gas flow, mixing region shear turbulence, surface and flotation zone quiescence, oil droplet re-emulsification and gas bubble size.

An IAF usually has four or more cells in series with a 1 min residence time per cell. This reduces flow short-circuiting, thereby improving separation efficiency. Water enters the first active flotation cell via a feedbox, and passes from cell to cell via underflow weirs in the connecting bulkheads. Floated oil is removed separately from each cell. Dispersed oil droplet concentration in the influent should typically be no greater than 500 ppm on a long-term basis of which approximately 50% is removed by each cell, the percentage removal efficiency increasing with the influent oil droplet concentration for a fixed residence time. The treated water finally enters a quiescent discharge cell with an approximately 1 min residence time where separation continues as gas bubbles, still entrained in the water leaving the last cell, rise to the surface. Individual IGF machines are typically available in different sizes to treat feed flows of between 50 and 5000 gpm (Figure 3).

The performance of the IGF process has been extensively investigated, and proprietary predictive mathematical models derived. In the context of the trials, the most influential variables in IGF, listed in order of decreasing importance, are:

- water-treating chemical concentration;
- feed water flow rate (relates to residence time);
- impeller speed (increasing the speed will ingest more air and increase power consumption with relatively little change in fluid circulation);
- impeller submergence (distance between the liquid surface and the top of the rotor. Increased submergence increases power draw, whilst reducing

Figure 3 Longitudinal cross-section of mechanical induced gas flotation machine. Courtesy of Baker Process.

gas injection and increasing the liquid recirculation rate. Typically 200 mm);

- impeller engagement (distance from bottom of the impeller to top of draft tube. Engagement is positive if the rotor is in the tube and negative if it is above the draft tube. Influences liquid circulation. Typically 50 mm.

The order of this list may vary for different applications since removal efficiency is a strong function of the type of crude oil and the chemical composition of the feed water.

The IGF is a relatively low retention time (4–6 min) device using relatively large volumes of gas (compared to DAF) at near ambient pressure. The gas dispersion in these cells is so effective that retention times are relatively short, allowing a reduction in equipment size compared to the DAF method. The process operates at near atmospheric pressure. Both these factors give the IGF process a significant economic advantage over the DAF.

Induced Static Flotation Unit (ISF)

Since the IGF was originally developed for the mining industry, the power required by the impeller needed to be sufficient to suspend solids of perhaps 0.2–0.3 mm in diameter at concentrations of 30–40% solids. As solids removal is not the dominant process in oily water treatment, solids suspension capability can be reduced in order to achieve low turbulence in the flotation vessel at reduced power. This has led to the development of hydraulic rather than mechanical induction of bubbles (see **Figure 4**). The ISF generates bubbles hydraulically using an eductor operating under pressure, usually 60 psig rather than mechanically. Feed is added directly to

the flotation vessel. Clarified effluent water is recycled through a header, and gas is drawn from the vapour space by a Venturi effect. The resultant gas–liquid mixture is directed against a striker plate, which causes the formation of numerous small bubbles that are distributed across the full cross-section of the cell. The circular cross-section of the vessel improves the uniformity of the bubble distribution in the flotation vessel, which improves the probability of bubble–droplet collision.

Unlike the IGF, the ISF operates under pressure. Pressure operation has the advantage that hazardous (hydrogen sulfide) or environmentally sensitive gases (hydrocarbons, carbon dioxide) are contained. It has also eliminated the need for transfer pumps for the clarified water effluent and the requirement for mechanical skimmers to remove the floated oil.

The ISF design reduces the number of moving parts, while maintaining performance similar to the industry-standard mechanical units. Operation of the ISF with a centrally mounted skim trough and skim cycle timers has provided the means to reduce the skim volume to less than 1% of the forward flow in most cases. It also uses less power than the mechanical IGF. All machine adjustments are external to the vessel, thereby ensuring operator safety in hazardous applications.

The use of eductors for inducing gas to generate gas bubbles in the flotation process was first patented in the mid-1970s. Initially, ISF performance was poor compared to mechanical flotation units. The design was improved by employing a cylindrical pressure vessel, centrally mounted skimmings trough for use on floating platforms and an improved eductor configuration. The most common version of the ISF has four cells, hydraulically connected in series. Increases in the clean water recycle rate will cause

Figure 4 Eductor for hydraulic induced static flotation machine. Courtesy of Baker Process.

a progressive reduction in residence time throughout the unit, which may result in reduced bubble-droplet collision efficiency. The clean water recycle rate may be reduced by operating at a high nozzle pressure (50–100 psi).

The key features of the hydraulic flotation machine are shown in the cut-away view in Figure 5.

Comparison of DAF and Induced Processes

Dissolved and induced processes differ in a number of key parameters.

1. The amount of gas transferred to the process water is relatively small in the DAF process, approxi-

Figure 5 Hydraulic induced static flotation machine. Courtesy of Baker Process.

ately 20–40 times less than that used by the IGF process.

2. Because the DAF works by dissolution of gas in water it is sensitive to water temperature (increased temperature reducing gas solubility). By comparison, induced processes are relatively temperature insensitive. In fields where hot water or steam floods are used to recover oil, temperatures above 40°C will significantly reduce the performance of a DAF unit.
3. The means of bubble generation and mixing differs (pressure let-down in DAF vs mechanical or hydraulic induction in the IAF and ISF, respectively). Gas dissolved in the water is insignificant in process terms in the induced mechanisms since there is no pressure let-down.
4. When scaling up the process, residence time is the key variable for the IGF. For the DAF it is hydraulic loading (total process water feed divided by the vessel surface area). Hydraulic loading is related to plant floor space.

The advantages of DAF are:

1. Often lower power requirement than IGF.
2. Lower volume of skimmings as a percentage of the forward flow (1–5% for DAF systems as compared with 2–10% for mechanically induced gas systems. ISF skimmings volume compares favourably with that of DAF, being approximately 1% of the forward flow).
3. Smaller volumes of sludge may be formed than with IGF, especially where organic rather than inorganic (metallic) polyelectrolytes are used to aid flotation.
4. Better handling of suspended solids. DAF will allow the use of metal salts for coagulation and flocculation. The DAF flotation cell can also be fitted with a bottom skimmer for solid that can settle.

Advantages of induced processes are:

1. Relatively low capital cost.
2. Relatively small equipment footprint (single skid-mounted unit vs a multicomponent system).
3. Volatile organic carbons (VOC) are contained within the flotation cell. Not all DAF units use closed top flotation cells.
4. Varied flows can be handled easily.
5. Due to their high mechanical reliability, no standby capacity is required.
6. Loss of one cell will not significantly reduce separation efficiency, allowing on-line maintenance of impeller mechanisms.
7. Lower chemical consumption, since flocculation is not necessary.

In certain applications, such as removal of mineral oils from a steel rolling mill effluent, induced and dissolved process have been used in series.

Chemical Selection

From a chemical addition standpoint the two types of flotation differ due to the size of the bubble each creates:

- induced gas typically creates a relatively large gas bubble in the 10–2000 μm range;
- dissolved gas typically creates a relatively small gas bubble in the 1–100 μm range.

Dissolved Gas

In this instance, chemical treatment is used to flocculate the oil droplets and solid particles. The larger the floc, the more gas bubbles are trapped underneath the floc structure. The flotation process is significantly more quiescent than the induced processes, hence does not tend to break up flocs. Separation is therefore based on the amount of bubbles that are trapped underneath the floc, and the maintenance of uniform flow distribution to avoid floc shearing. The influent/gas bubble carrier flow distributor and mixing chamber design determines the efficiency of a DAF unit.

Ferric compounds work in a similar way to cationic polymers except where polymers are specific to the charge on the oil droplet; metal salts swamp the bulk solution leading to charge destabilization by disassociating on addition to water. As a result, the dose rate is typically higher than for a solution polymer. The solubility of metal ions is limited and hence they tend to generate weak flocs, which means that they are better used as part of a two-stage treatment, usually in conjunction with an anionic polymer. As an example, one facility described by Berne and Cordonnier uses 10 mg L^{-1} aluminium sulfate with 1 mg L^{-1} anionic polyelectrolyte. However, this does result in a large volume of sludge, 10–30 $\text{m}^3 \text{day}^{-1}$ in this case. Use of organic coagulants alone can significantly reduce sludge volumes (3–5 $\text{m}^3 \text{day}^{-1}$ in this example).

Induced Gas

The objective of chemical treatment is to change the surface charge of either the gas bubble or the oil droplet in order to cause adhesion between them after collision. The size ratio of the bubble-to-oil droplet is usually $\leq 1 : 1$. The only solids that are floated are those whose surface charge is opposite to that on the bubble surface, or those that are associated with, and contained in, the oil droplet. For this reason, induced processes may only remove 55–75% solids from the

forward flow as compared with 95–98% oil droplet removal. No attempt is made to flocculate oil droplets and solid particles, because the mixing intensity in the units will tend to break up any floc structure that has been formed.

In general, oil droplets and other suspended material will be negatively charged. Addition of cationic polymer neutralizes the charge on the oil–gas species, while a long-chain polymer collects the contaminant in preparation for removal. Most cationic polymers work best in the pH range 6–9. If the pH falls outside this range, pH adjustment of the wastewater may be required. Overall removal rates are around 90% without chemicals up to 98% with chemicals. In order to size a unit for commercial use, laboratory studies are conducted to determine the effect of variables such as rotor speed, chemical addition and feed rate on oil removal, all of which have an impact on the rate constant K . The data are then fed into proprietary models based on the Klimpel model, which contain correction factors for scaling up the equipment. The models have been validated using numerous sets of data from commercial installations. Oil–water separation is enhanced by using an emulsion breaker, a cationic high charge density, low molecular weight coagulant polymer. The polymer is distributed throughout the continuous (water) phase where it neutralizes the anionic charge at the oil–water interface. This destabilizes the emulsion, allowing oil droplets to coalesce by collision with one another.

Cationic solution polymers would usually be applied as a 1–10% solution with a dose rate of 2–30 ppm. Emulsion polymers (tightly coiled polymer molecules entrapped in solvent, activated by dilution in water) are applied at concentrations no greater than 1–2% at dose rates of 0.5–5.0 ppm.

Future Developments

Hydrocyclones and Flotation

Flotation was practised extensively on fixed offshore platforms throughout the 1970s and 1980s to clean-up produced water prior to overboard discharge. As the volumes of produced water have increased with field life, water-handling facilities have become constrained. Operators have retrofitted produced water processing capacity using hydrocyclones rather than flotation machines, because the former have a smaller footprint per volumetric flow rate of produced water treated. However, flotation oil–water separation technology has a place on offshore platforms as a polishing stage for produced water clean-up following initial treatment by hydrocyclones. One design uses what is in principle a dissolved air flotation vessel downstream of the oil–water separation hydrocyclones.

Motion Insensitive Flotation

With the increased use of floating production facilities, the motion experienced by flotation devices

Figure 6 Single cell ISF. Courtesy of Baker Hughes Process Systems.

inhibits separation. A 2° tilt results in one end of a 12 m long flotation machine being approximately 350 mm higher than the other end of the vessel. This results in one end of the machine flooding while the other end will not remove floated oil. To overcome this problem, one manufacturer has designed a flotation column ISF machine that reduces the impact of pitch and roll to 10 mm at 2° tilt.

The method of bubble generation (eduction) is the same as that used for the four-cell ISF. Sparging was investigated as an alternative, however the bubbles were larger and moved in a linear fashion to the surface. Educated air forms smaller bubbles and exhibits random movement. Both these latter characteristics are desirable as they increase the chance of an air bubble–oil droplet collision.

Since the single-cell ISF has one rather than four cells, theory would predict that its contaminant removal efficiency would be reduced from approximately 90–98% for a four-cell unit to 80–90% for a single cell unit, primarily because the residence time in the single cell unit is some 65% of that in the traditional four cell design. In trials, however, the unit has operated successfully with inlet oil concentrations of between 50 and 1300 ppm, and suspended solids concentrations of 10–50 ppm, and has achieved oil removal efficiencies comparable to the four-cell model, taking into account the reduced residence time in the single cell. In service, actual efficiencies will depend on optimization of flow regime and chemicals (see Figure 6).

Introduction

Aeration of slurry is a key element in a flotation system. The extent of aeration influences the perfor-

mance of flotation machines and the overall recovery process. Flotation can, in general, be divided macroscopically into two subprocesses: selective collection of hydrophobic particles by air bubbles, and separation of bubble/particle aggregates from the pulp containing hydrophilic particles. The method and location of aeration or bubble generation control the mechanism of particle collection by either collision with and subsequent attachment to bubbles, or *in situ* bubble formation on hydrophobic particle surfaces. A flotation machine should be designed to provide an

optimal aeration condition for efficient particle collection and a suitable hydrodynamic environment for effective transfer of bubble/particle aggregates from the remaining pulp. Unfortunately, conflicting hydrodynamic environments are usually required for these two sub-processes. It is often difficult – if not impossible – to evaluate theoretically the relative contributions of individual collection mechanisms in a particular flotation device. The limited understanding of the aeration mechanisms in flotation processes is partly responsible for the development of more than 200 flotation cell designs over the years. Many of these designs are not subtle variations in basic hardware, but variations in design principles. Therefore, knowing where and how collection occurs and which aeration method is suitable for a particular application is an important step in a more scientific approach to flotation cell design.

Aeration methods used in flotation can be conveniently categorized as air dispersion and air dissolution. In the air dispersion approach, a stream of air is dispersed into slurry to achieve suitable sizes and population of bubbles. This is accomplished by shearing the air stream into bubbles under mechanical agitation as in mechanical flotation machines, or using in-line static mixers as in Microcel and packing materials as in packed columns. Air can also be dispersed through porous spargers, as used in pneumatic flotation machines or conventional Canadian flotation columns.

With the air dissolution method, on the other hand, the air is dissolved under a pressure of 3–5 atm into slurry for subsequent gas nucleation (or gas precipitation) and cavitation. Bubble formation is then achieved by either releasing gas-supersaturated slurry to atmospheric pressure as in dissolved air flotation, or decreasing the pressure of slurry by aspiration as in vacuum flotation.

Dispersed air flotation is widely used in minerals processing with relatively coarse particles (larger than 20 μm) and high slurry densities (greater than 30% solids). Other areas of applications include solid cleaning, de-inking from recycled paper and bitumen recovery from oil sands. Dissolved air flotation is suitable for municipal water and industrial effluent treatment, due to its capability of generating relatively fine bubbles of less than 100 μm required for recovering particles finer than 10 μm at a slurry density of less than 0.5% solids.

An emerging trend is to integrate the useful features of dissolved air flotation into dispersed air flotation. The combination of the two bubble-generating mechanisms has led to a new flotation cell design. Traditionally, slurry aeration and flotation separation are performed in the same vessel. Feed aeration followed

Figure 1 Schematic illustration of the concept of a flotation system consisting of a reactor and a separator.

by flotation separation in a separation vessel (a reactor–separator design), has been evolved with demonstrated higher flotation kinetics. The concept of a flotation system consisting of a reactor and a separator is illustrated in **Figure 1**. The reactor is a vigorous bubble/particle contacting device where particle collection takes place with bubbles formed by both air dispersion and nucleation/cavitation mechanisms. The separator is a quiescent bubble/pulp separation device where the hydrodynamics favour the separation of bubble/particle aggregates from the pulp with essentially no or little turbulence.

With continuing improved understanding of particle/bubble collection mechanisms and the role of aeration in flotation, it is anticipated that pre-aeration of feed will become an important component in modern flotation circuits as a means of increasing flotation kinetics and improving selectivity of fine particles. This article focuses on the fundamentals and recent developments in pre-aeration of feed used in mineral flotation.

Fundamental Basis of Feed Aeration

A theoretical analysis of aeration in a flotation system is complicated. As a result, the development of aeration techniques in flotation is largely based on phenomenological correlations. The feed aeration and subsequent particle collection during the aeration are the combination of features of dispersed and dissolved air flotation. Particle collection by air bubbles in flotation is a multi-step process, involving three phases with interactions among solid/liquid, solid/gas and liquid/gas in the presence of various inorganic and organic species under economical and mechanical constraints. At least two particle collection mechanisms have been considered in flotation.

Direct Contact of a Particle with a Bubble

In this collection process, a particle encounters a bubble, either by relative motion or the turbulence

in a flotation system. The probability of the particle being captured by the bubble (P) can be expressed as:

$$P = P_c P_a P_d \quad [1]$$

where P_c , P_a and P_d are the probability of bubble/particle collision, attachment and detachment, respectively. For a hydrophobic particle, bubble/particle collision determines the particle collection rate governed by hydrodynamic conditions. Hydrodynamic analysis showed that the collision probability between a descending particle with an ascending bubble is given by:

$$P_c = a(d_p/d_b)^n \quad [2]$$

where parameters a and n are a strong function of hydrodynamic characteristics of the system. Eqn [2] shows that the probability of particle–bubble collision is proportional to the n th ($n \geq 1$) power of the solid particle size (d_p) and inversely proportional to the same power of the bubble size (d_b). For fine particles, small bubbles have to be used to obtain sufficient particle–bubble collisions. The direct contact was analysed between a descending fine particle of $d_p = 10 \mu\text{m}$ and a rising swarm of bubbles in a flotation column. A collection zone as tall as 10 m was determined to be essential to ensure at least one collision of the particle with a bubble. This implies an inefficient collection process under conventional column flotation conditions.

To increase the particle–bubble contact frequency, a relatively high turbulence or energy dissipation rate is required, as in mechanical flotation machines. The number of particle–bubble collisions per unit volume and time in a highly turbulent flowing fluid (Z_{pb}) can be expressed as:

$$Z_{pb} = 5N_p N_b [(d_p + d_b)/2]^2 (V_p^2 + V_b^2)^{0.5} \quad [3]$$

where N_p and N_b are the number concentrations of particles and bubbles in the pulp. V_p and V_b are the mean relative velocities of the particles and bubbles (with reference to fluid), which are given collectively by:

$$V_i = 0.33\epsilon^{4/9} d_i^{7/9} (\Delta\rho/\rho)^{2/3} / \nu^{1/3} \quad [4]$$

In eqn [4], subscript i refers to bubble or particle, ϵ is the specific energy dissipation rate, $\Delta\rho$ is the difference in densities of particle i and liquid medium, ρ is the medium density, and ν is the kinematic viscosity. This equation shows that a high energy dissipation rate favours particle–bubble collision. However, vigorous agitation as in mechanical flotation machines

may break particle–bubble aggregates, thereby increasing the probability of particle detachment from bubbles and hence decreasing the overall collection rate. In addition, the back mixing (or liquid circulation) caused by increased turbulence may hinder the transport of bubble–particle aggregates out of the turbulent zone, contributing to low flotation kinetics. The incentive to separate the two functions of a flotation machine, i.e. aeration and separation, is evident, as reflected in the reactor–separator design.

In Situ Bubble Nucleation on Hydrophobic Particles

With this mechanism, gas nucleates and bubbles form selectively on hydrophobic particles. The theoretical basis of flotation by gas precipitation or nucleation was proposed in the 1960s and has recently been extended to hydrodynamic cavitation. The gas nucleation mechanism has been used to account for particle–bubble collection in dissolved air flotation. An advantage of this mechanism over a conventional particle–bubble contact mechanism is the elimination of a collision stage, a rate-limiting step in fine particle flotation. However, direct adoption of this technique to mineral flotation faces a number of challenges. Clearly, tiny bubbles in the micro and submicron range generated solely by a gas nucleation mechanism are not sufficient to float coarse mineral particles effectively. However, the collision probability of larger bubbles with the particle–tiny bubble aggregates in the quiescent region may increase. The limited number of bubbles that can be generated by gas nucleation from a supersaturated system does not provide sufficient carrying capacity to float large amounts of solids. To improve solid recovery rates, large volume slurry saturation tanks are needed, presenting extra capital and operating costs.

Alternatively, tiny bubbles and cavities can be formed by the reduction of pressure in a fast-flowing fluid, as indicated by Bernoulli's equation:

$$P_1 + (1/2)\rho U_1^2 = P_2 + (1/2)\rho U_2^2 = C \text{ (constant)} \quad [5]$$

in which U is the water flow velocity at a point where the pressure is P , and ρ is the density of liquid. If the liquid flow velocity exceeds a critical value, the pressure in the liquid stream reduces to a value where the liquid pressure falls below its vapour pressure, at which point cavities form which expand to relieve the differential pressure, a phenomenon called hydrodynamic cavitation. The presence of solids enhances hydrodynamic cavitation due to the increased turbulence and pressure fluctuations around particles in the stream. As in gas-supersaturated systems, cavities would form preferentially on hydrophobic particles

relative to energetically unfavourable hydrophilic solid-liquid interfaces. The principal advantage of exploring hydrodynamic cavitation in flotation is that gas supersaturation of slurry is not required and additional air can be introduced into the system for air dispersion. As a result, hydrodynamic cavitation can be readily implemented in mineral flotation systems.

A convenient way of aiding bubble nucleation and cavitation is by aeration in the feed slurry line. The existence of gas nuclei in water has been demonstrated in coagulation, sedimentation and filtration tests using fine coal and silica with a medium particle size of 5 and 1.5 μm , respectively. The size of gas nuclei in natural water was estimated to be 10 μm . When forcing the water through the tip of a cavitation tube at a flow velocity above 8–15 m s^{-1} , micro-size bubbles were observed to form. Numerical simulation confirmed that, at this flow velocity, a pressure close to liquid vapour pressure was attained inside the tip of the cavitation tube, suggesting the formation of bubbles by the expansion of the pre-existing gas nuclei and subsequently filled with liquid vapours. Using a light attenuation method, the onset velocity of bubble formation by hydrodynamic cavitation was found to be dependent on the diameter and length of the nozzle, slurry temperature and initial gas content. With gas-supersaturated water, for example, the onset velocity reduced from 15 to 7 m s^{-1} . Adding frother into liquid does not affect the onset of bubble formation by cavitation, but it increases the bubble stability. Sebba has reported the formation of stable bubble swarms of approximately 25–50 μm which he called aprons, generated similarly. Adding a small amount of air into the flowing liquid stream enhanced

bubble formation at a reduced liquid flow velocity, which provides a direct justification for feed aeration by hydrodynamic cavitation.

Applications of Feed Aeration

There are many new flotation devices that make use of the combined features of dispersed and dissolved air flotation. Feed slurry aeration through the concept of reactor and separator design fully exploits the combined mechanisms of bubble generation (dispersed/dissolved). Some of these flotation devices are reviewed here.

Venturi Aerated Column

The Venturi aerated column (VAC) was designed based on the concept of reactor and separator design (Figure 2). In this case, the reactor is a Venturi tube where air/slurry contact takes place. The separator is a column of length 1–2 m. The partial recirculation of tailings slurry was used to intensify the slurry jetting action, facilitating bubble size control (typically 500–800 μm) and bubble/particle interaction.

Figure 3 presents a direct comparison between a laboratory Denver cell and a single VAC cell in batch tests for a nickel sulfide ore. The VAC cell gave a higher concentrate grade at the same nickel recovery. Two VAC cells in series (as a rougher-scavenger configuration) were tested in an operating plant treating nickel sulfide ores. Compared to the mill rougher flotation, superior metallurgy was obtained with the VAC cells. With two VAC cells in series, similar metallurgical performance to the plant multi-stage

Figure 2 Schematic of a Venturi aerated column (VAC).

Figure 3 A direct comparison in nickel grade/recovery performance between a batch Denver cell and a batch VAC cell. Squares, column; diamonds, column (repeat); triangles, Denver; circles, Denver (repeat).

flotation circuit was achieved, as shown in **Figure 4**. The VAC cell has also been tested and found to be successful in de-inking applications of recycled paper pulp with the performance exceeding the existing plant circuit in terms of fibre recovery at comparable brightness.

Cavitation Tube

Based on the principle of nucleation, a cavitation tube (Figure 5) similar to the Venturi tube was developed and tested in association with a mechanical cell. As shown in **Figure 6** for fine silica flotation (less than $5\ \mu\text{m}$), silica recovery of 30% was obtained in the mechanical cell under conventional operating conditions (no cavitation tube). By installing a cavitation tube in the feed slurry line, silica recovery was increased significantly, depending on the slurry velocity

Figure 4 Comparison in nickel metallurgy between a plant rougher flotation circuit and two VAC cells in series. Squares, two VAC cells, circles, mill overall daily; triangles, mill roughers.

Figure 5 Schematic of a cavitation tube on the feed line before a mechanical cell.

through the nozzle. The improved recovery is clearly due to the bubble formation and particle collection by gas nucleation/cavitation. Addition of a small amount of air into the feed slurry (less than 7%) before the cavitation tube further increased silica recovery, indicating that the combined mechanisms of bubble formation by dispersed/dissolved air were beneficial to fine particle flotation. In-plant testing using a similar set-up demonstrated an improved flotation performance of Cu/Ni separation.

Other Devices and Processes Using Feed Slurry Aeration

Jameson cell The innovative design of the Jameson cell is based on the point of air addition and bubble generation. It utilized the concept of reactor and separator design. The downcomer into which air is aspirated and particle collection occurs is the reactor, while the cylindrical tank is the separator. The feed under high pressure is introduced at the top of the downcomer through a nozzle, producing a high speed slurry jet which entrains air into the downcomer. In

Figure 6 Fine silica recovery vs slurry velocity through the nozzle of a cavitation tube. Conditions: 1 wt.% silica ($< 5\ \mu\text{m}$); 10 p.p.m. Dowfroth 250; $1.25 \times 10^{-4}\ \text{mol L}^{-1}$ DAH; pH = 7.5–7.8; air flow rate in the mechanical cell $= 2\ \text{L min}^{-1}$.

addition to its successful use in sulfide minerals and coal flotation, the Jameson cell has also been adopted in de-inking applications for the paper industry.

Davcra cell The Davcra cell is a type of pneumatic machine, employing feed slurry aeration. Air and feed slurry are injected into the separating tank through a cyclone-type dispersion nozzle. Air dispersion and particle collection take place in the nozzle and in the highly turbulent region in the separation tank, which is separated by the quiescent zone. A limited application has been reported.

Low energy extraction process for bitumen extraction from oil sands In bitumen extraction from Athabasca oil sands, Syncrude Canada recently adopted a low energy extraction process with hydro-transport of oil sand slurries. Oil sand slurry is transported from the mine site via pipelines (3–5 km) with a relatively high slurry velocity (4 m s^{-1}). Air is injected into the pipelines. The aerated oil sand slurry is then introduced into primary separation vessels through a tangential entry feed well. Bitumen droplets attached to air bubbles float to the top of the remaining slurry to form a primary froth. Wash water is added under the froth to reduce the amount of solids reporting to the bitumen froth. Here, hydro-transport pipelines function as a reactor to increase the bubble-bitumen contact frequencies. This technique has been implemented in operation.

The Microcel, German Bahr's cell, rapid flotation cell, Contact cell, Centrifloat cell, and air-sparged hydrocyclone are other examples employing feed slurry aeration and the concept of reactor and separator design.

Concluding Remarks

With increased understanding of the role of aeration in flotation, a new trend in flotation machine design has been established. The selection of aeration in flotation is closely related to particle collection mechanisms and, to some extent, to operation and maintenance costs. Aeration in flotation has evolved from air dispersion using direct particle-bubble contact mechanism, to *in situ* bubble formation on hydrophobic particles by gas nucleation and cavitation in dissolved air flotation. The emerging trend is a combination of the two. The location of aeration has also been evolved from slurry aeration in a flotation vessel to feed aeration in a virtual reactor followed by flotation separation in a separation tank.

Flotation is an energy-dependent process and, like all the subprocesses – solid suspension, aeration, particle-bubble interaction and bubble formation – are

energy-dependent. Part of the energy dissipation in flotation systems can be attributed to the method of aeration. Ideally, as much of the input energy as possible should be directed to the main function of flotation: particle collection by bubbles. Feed aeration is associated with significant energy dissipation efficiency as the input energy is distributed evenly in slurry in contrast to mechanical cells, in which the energy is concentrated in the impeller region. The energy used for pumping, on the other hand, is a major energy requirement not needed in the existing collection processes. With the concept of feed aeration, pumping energy is utilized to force feed slurry through a hydrodynamic cavitation tube (or a Venturi tube), which facilitates the *in situ* generation of bubbles on hydrophobic particles. It is an exciting design challenge to develop energy-efficient feed aeration flotation systems.

Introduction

Adsorption of surfactants on minerals is the basic process governing flotation. It is controlled by various physicochemical processes in the pulp involving interactions among the mineral particles, surfactants, dissolved inorganics, solvent species and other additives such as polymers. Adsorption can be considered as selective partitioning of the surfactant adsorbate into the interfacial region, resulting from the more energetically favourable interactions between the adsorbate and the solid than those between the former and the species in the bulk solution. The interactions leading to adsorption include chemical bonding, electrostatic interaction, desolvation of the surfactant polar group and the mineral surface species, hydrogen bonding, van der Waals interactions, etc.

Water chemistry plays an important role in the adsorption process by affecting the surfactant–solution equilibria, the mineral–solution equilibria

and subsequently the interactions between the surfactants and the mineral particles. The interactions in mineral–solution system include dissociation, micellization and precipitation of the surfactant, dissolution of a small amount of solids followed by hydrolysis, complexation and precipitation of the dissolved species, and the interactions between dissolved mineral species with surfactant in the bulk in various forms. The dissolved species, including those introduced due to dissolution from all the minerals present in the ore and those from the water source, fresh and recycled, are the major elements that affect the water chemistry. While impurities introduced from water can be controlled to some extent, the chemical species released into the system due to dissolution from the minerals cannot be avoided. In systems containing soluble or sparingly soluble minerals where the extent of dissolution is markedly higher than that in most oxide/silicate systems, the effect of dissolved mineral species can be drastic. Understanding the mineral–solution–surfactant chemical equilibrium under different physicochemical conditions is critical for developing reagent and processing schemes for separation.

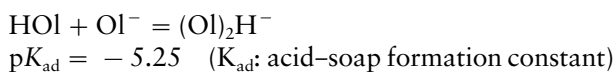

Phosphate is one of the most important minerals processed by flotation techniques. Flotation is efficient for the beneficiation of phosphate ores with silicate gangues, but those with carbonaceous gangues are difficult to separate by flotation techniques. The low selectivity has been attributed to the similarities in the surface chemical properties of the constituent minerals. These properties, in turn, are influenced by the water chemistry of the surfactant–mineral systems. In this section the effects of water chemistry on the surfactant–solution equilibrium, the mineral–solution equilibrium, the surfactant–mineral interactions in the separation of phosphate and associated minerals are discussed. Methods to manipulate and control the solution chemistry to achieve selectivity in flotation are also examined.

Water Chemistry of Flotation Reagents

Long chain fatty acids such as oleic acid are among the commonly used reagents for the flotation of oxides, silicates and salt-type minerals. Flotation of these minerals using fatty acids is affected greatly by solution properties such as pH, since weakly acidic fatty acids undergo association interactions that can influence their adsorption and flotation properties. For example, oleic acid species will undergo dissociation

to form ions (Ol^-) at high pH values and exist as neutral molecules (HOl) at low pH value. In the intermediate region, the ionic and the neutral molecular species can associate to form ion–molecule complexes ($(\text{Ol})_2\text{H}^-$). As the surfactant concentration is increased, micellization or precipitation of the surfactant can occur in the solution. In addition, surfactant species can associate to form other aggregates such as the dimer (Ol_2^{2-}) in premicellar solutions. Also, long chain fatty acids such as oleic acid have very limited solubility, which is a sensitive function of pH. The pH of precipitation of oleic acid calculated as a function of total oleate is shown in Figure 1.

The solution equilibria of oleic acid (HOl) are expressed as below:

The species distribution of oleic acid as a function of pH based on the above equilibria at a given concentration is shown in Figure 2. It can be seen from this figure that:

1. The pH of the precipitation of oleic acid at the given concentration is 7.45.
2. The activities of oleic monomer and dimer remain almost constant above the precipitation pH and decrease sharply below it.
3. The activity of the acid–soap $(\text{Ol})_2\text{H}^-$ exhibits a maximum in the neutral pH range.

The surface activities of the various surfactant species can be markedly different from each other. It has been estimated that the surface activity of the acid–soap $(\text{Ol})_2\text{H}^-$ is five orders of magnitude higher than that of the neutral molecule (HOl) and about seven orders of magnitude higher than that of the neutral molecule (HOl) and about seven orders of magnitude higher than that of the oleate monomer Ol^- .

The existence of salt will also affect the surfactant–solution equilibria by changing the surface activities of the various surfactant species, the critical micelle concentration and the solubility of the surfactant, and the solvent properties of the solution.

Figure 1 pH of oleic acid precipitation. (From Morgan LJ, Ananthapadmanabhan KP and Somasundaran P (1986) Oleate adsorption on hematite: problem and methods. *International Journal of Mineral Processing* 18: 39. Copyright: Elsevier Science.)

Figure 2 Oleate species distribution as a function of pH. Total oleate concentration = $3 \times 10^{-5} \text{ mol L}^{-1}$. (From Ananthapadmanabhan KP and Somasundaran P (1980) Oleate chemistry and hematite flotation. In: Yarar B and Spottiswood DJ (eds) *Interfacial Phenomena in Mineral Processing*, p. 207. New York: Engineering Foundation.)

It is clear that, to understand the adsorption of reagents on solids, the effects of concentration, pH, ionic strength and activities of the various possible reagent species on the adsorption process need to be taken into account.

The Effect of Water Chemistry on Mineral–Solution Equilibrium

When mineral particles are in contact with water, they undergo dissolution, the extent of which is dependent on the type and concentration of chemicals in solution. The dissolved mineral species can undergo further reactions such as hydrolysis, complexation, adsorption and precipitation. The complex equilibria involving all such reactions can be expected to determine the interfacial properties of the minerals and their flotation behaviour. The equilibria that con-

trol the dissolution of calcite and apatite in water are given in Table 1.

In the case of carbonaceous phosphate minerals, apatite, calcite and dolomite will dissolve in water, followed by pH-dependent hydrolysis and complexation of the dissolved species. Since these minerals are sparingly soluble, the dissolved species have a marked effect on their interfacial properties.

It should be noted that, from theoretical considerations, depending on the solution conditions, the surface of apatite can be converted to calcite and vice versa through surface reactions or bulk precipitation of the more stable phase. The stoichiometry of the equilibrium governing the conversion of apatite to calcite can be written as:

It can be seen from this equation that, depending on the pH of the solution, apatite can be converted to calcite if the total carbonate in solution exceeds a certain value. In fact, the amount of dissolved carbonate from atmospheric CO_2 does exceed that required to convert apatite to calcite under high pH conditions.

Surface conversion due to the reaction of the dissolved species with the mineral surface can be predicted using stability diagrams for heterogeneous mineral systems. This is illustrated in Figure 3 for the calcite–apatite system. The activity of Ca^{2+} in equilibrium with various solid phases shows that the point of interception for calcite and apatite is pH 9.3. Above this pH, apatite is less stable than calcite and hence conversion of apatite to that of calcite can be expected in the calcite–apatite system. Similarly, apatite is more stable than calcite below pH 9.3. It is to be noted that Ca^{2+} in equilibrium with calcite in an open system (open to atmospheric CO_2) is significantly different from that in a closed system. Also,

Figure 3 pH dependence of activity of Ca^{2+} in equilibrium with calcium oleate (dotted line: $\text{Ol}_T = 10^{-4} \text{ kmol m}^{-3}$), calcite (open (closed lines) and closed (dots and dashes) systems) and apatite (dashed lines). (From Ananthapadmanabhan KP and Somasundaran P (1984) The role of dissolved mineral species in calcite-apatite flotation. *Mineral and Metallurgical Processing* 1: 36.)

in the absence of atmospheric CO_2 , apatite has a wider stability region than in the open system. Atmospheric CO_2 can thus be expected to play an important role in these types of mineral-solution equilibria and in operations dependent on interfacial properties.

Figure 4 Illustration of the effect of supernatants on the zeta potential and isoelectric point of calcite and apatite: $2 \times 10^{-3} \text{ kmol m}^{-3} \text{ KNO}_3$. Open circles, calcite in water; open triangles, apatite in water; filled triangles, apatite in calcite supernatant; filled circles, calcite in apatite supernatant. (From Ananthapadmanabhan KP and Somasundaran P (1984) The role of dissolved mineral species in calcite-apatite flotation. *Mineral and Metallurgical Processing* 1: 36.)

The surface conversions in the calcite-apatite system have been proved experimentally; electrokinetic data obtained for the calcite-apatite system in water and in the supernatant of each other are shown in **Figure 4**. When apatite is in contact with calcite supernatant, its zeta potential is seen to shift to that of calcite and vice versa, suggesting surface conversion of apatite to calcite and calcite to apatite, respectively.

The zeta potential data obtained in mixed supernatants of calcite and apatite also show the effect of dissolved mineral species. If supernatants of calcite and apatite are combined as a 1 : 1 mixture, the two minerals have almost identical surface charge characteristics in the basic pH range (**Figure 5**).

The surface conversion of apatite and calcite is further supported by the result of electron spectroscopy for chemical analysis (ESCA) measurements. The results in **Figure 6** show that, when apatite is conditioned in the supernatant of calcite at $\text{pH} \sim 12$, its surface exhibits spectroscopic properties characteristic of both calcite and apatite. This behaviour is attributed to the precipitation of calcite on the apatite.

Dissolution equilibria of sparingly soluble minerals play a major role in determining the surface properties of these minerals and in turn, adsorption of reagents on them.

The Effect of Water Chemistry on Adsorption of Reagents on Minerals

Chemical equilibria in aqueous solutions containing both the minerals and the surfactants can be expected to be much more complex than in either of the individual systems discussed above. In addition to surfactant adsorption at the solid-liquid interface, interactions between dissolved mineral species with various surfactant species can be expected. All these interactions can affect the surfactant adsorption and the subsequent flotation.

As indicated earlier, oleic acid has a very low solubility and adsorption of oleate, in some cases, is in fact precipitation of the surfactant in the interfacial region. In Figure 3, the activity of Ca^{2+} in equilibrium with various solid phases is plotted. If, at any stage, activity of Ca^{2+} in solution is greater than that

in equilibrium with Ca^{2+} -oleate, Ca^{2+} -oleate can be expected to precipitate.

Depletion isotherms of oleic acid on both francolite and dolomite has been observed to be a two-region linear isotherm with a change of slope at about $10^{-4} \text{ kmol m}^{-3}$ (Figure 7). Simultaneous analysis of the dissolved mineral species in the supernatants of the samples used in the adsorption experiments (Figure 8) shows a sharp decrease in the concentrations of both Mg and Ca species when oleate concentration exceeds $1.0 \times 10^{-5} \text{ kmol m}^{-3}$ in the case of francolite and $3.0 \times 10^{-5} \text{ kmol m}^{-3}$ in the case of dolomite. This suggests that bulk precipitation of calcium and magnesium species can occur under such conditions.

Major chemical equilibria for the precipitation of Ca and Mg species by oleate can be given as follows:

The onset of the precipitation of Ca(Ol)_2 and Mg(Ol)_2 is calculated from the solubility products given above and marked in Figure 8. The calculated oleate concentrations at the onset of precipitation are in good agreement with experimental observations.

It is postulated that, in the case of oleate adsorption on dolomite and francolite, different mechanisms govern the adsorption process. In the low concentration range ($< 10^{-4} \text{ kmol m}^{-3}$), the adsorption

Figure 7 Depletion isotherms of ^{14}C -labelled oleic acid on francolite (squares: pH = 8.2) and dolomite (circles: pH = 9.2). (From Somasundaran P, Xiao L and Wang D (1991) Solution chemistry of flotation of sparingly soluble minerals. *Mineral and Metallurgical Processing* 8: 115–121.)

Figure 8 Dissolved Ca (squares) and Mg (circles) levels from (A) francolite (pH = 8.2) and (B) dolomite (pH = 9.2) suspensions as a function of oleate concentration. (From Somasundaran P, Xiao L and Wang D (1991) Solution chemistry of flotation of sparingly soluble minerals. *Mineral and Metallurgical Processing* 8: 115.)

of oleate on both minerals occurs mainly due to chemical bonding on surfaces without any precipitation. At an intermediate concentration of about $10^{-4} \text{ kmol m}^{-3}$, the solubility limit of Ca and Mg oleate can be reached in the interfacial region but not in the bulk solution, suggesting surface precipitation of oleate on both minerals. In the high concentration range ($> 5 \times 10^{-4} \text{ kmol m}^{-3}$), oleate depletion may be dominated in the case of both minerals by the precipitation of Ca and Mg species with oleate, on the mineral surface and in the bulk solution.

From the above discussion on apatite–calcite conversion, it is clear that a flotation separation scheme designed on the basis of the surface properties of a single mineral is not likely to perform satisfactorily. The effect of dissolved species of calcite and apatite on fatty acid flotation of both minerals has in fact been studied using mineral supernatant solutions containing various dissolved species. The flotation results are shown in **Figure 9**. Both supernatants of calcite and apatite are found to depress the calcite flotation by oleic acid in the tested pH range, with apatite supernatant exhibiting a greater depressing effect. Similar results have also been obtained for apatite flotation. The supernatants of calcite and apatite depress the apatite flotation under all tested pH conditions.

Studies on the dissolved species responsible for the observed effect revealed that, for calcite flotation, the depression role of apatite supernatant results from the combined effects of calcium species and the phosphate species in solution, while the depression role of calcite supernatant is mostly that of the calcium ion and possibly some carbonate ions. The depression due to calcium ion is caused by the de-

pletion of oleate owing to the precipitation of calcium oleate. In the case of apatite flotation, the depression is due to phosphate and carbonate species in solution. The adsorption of these ions on the surface calcium sites reduces the sites available for oleate adsorption which, in turn, lowers the hydrophobicity of the surface and so depresses the apatite flotation. Calcium oleate precipitation, in this case, does not occur to a significant extent due to the low concentration of oleic acid used in flotation. The above observations clearly show that water chemistry plays a crucial role in the flotation of apatite–calcite systems.

In addition to reagent complexation and precipitation, other reactions that occur in the bulk solution can take place in the interfacial region. For example, hemimicellization at a solid–liquid interface is a phenomenon that drastically affects the adsorption of collector reagents on solids.

Flotation is a dynamic process. In addition to the equilibrium effects associated with the water chemistry, it can also influence the adsorption kinetics of surfactants on the solid surfaces. Anionic conditioning is a unit operation that precedes rougher flotation and skin flotation of phosphates in Florida flotation plants. The effect of water chemistry on oleic acid adsorption on francolite during anionic conditioning has recently been studied in detail. In order to identify the effect of process variables on the adsorption, the experiment was carried out under both laboratory and plant conditions (**Table 2**).

The kinetics of oleic acid adsorption on francolite under both laboratory and plant conditions, using distilled water and plant water, is shown in **Figure 10**. The adsorption density and kinetics are quite different depending on the conditions and the

water. Under laboratory conditions, the adsorption in plant water is significantly lower than that in the distilled water. It is proposed that this is due to reagent loss resulting from the dissolved species in plant water precipitating the oleic acid. In contrast, under plant conditions, the adsorption behaviour of

oleic acid in plant water and distilled water is similar and adsorption densities are lower than those under laboratory conditions. The high solid/liquid ratio under plant conditions will reduce the adsorption density on the solids because of the much greater solid surface on to which the reduced total amount of

reagent in the water adsorbs. This will also result in a lower reagent concentration in solution reducing the precipitation effect. The intense agitation in the plant conditioner may also remove some of the bound reagent from the surface.

The adsorption isotherms of oleic acid on francolite under laboratory and plant conditions are compared in **Figure 11**. Adsorption is markedly higher under laboratory conditions than under plant conditions. On the other hand, under plant conditions the adsorption is similar in distilled water and plant water. This suggests that the effect of dissolved species is reduced under plant conditions.

From the above discussion, it can be seen that the adsorption of surfactant on a mineral is a complicated process involving interactions such as surfactant self-association, mineral dissolution, bulk precipitation, adsorption and surface precipitation. The interactions are further complicated by the kinetic effects of the various reactions.

Understanding the effect of the water chemistry on reagent adsorption offers opportunities to manipulate such processes by optimizing the contributing factors such as alteration of the surface properties, complexation of ions which cause precipitation of the surfactant, prevention or enhancement of collector adsorption and changes in the adsorption kinetics to achieve the desired selectivity in flotation.

In the anionic flotation of phosphate, Ca^{2+} affects the grade of phosphate by activating the quartz through formation of calcium-bearing precipitates at high pH. This detrimental effect can be prevented by adding sodium silicate, which can interact with Ca^{2+} and form calcium silicate. Since calcium silicate and quartz are negatively charged, detachment of calcium silicate from quartz can occur and thus quartz flotation can be depressed.

It has been found that in carbonate/phosphate systems, with fatty acid as collector, apatite is depressed in the acid medium (pH 5.5–6.0) while carbonate is floated. The depression of phosphate at this pH is possibly due to the adsorption (or formation) of aqueous CaHPO_4 on its surface, preventing surfactant ions from approaching the surface of the phosphate particles. Free Ca^{2+} in solution can affect the formation of aqueous CaHPO_4 . From thermodynamic considerations it can be predicted that the selective flotation of carbonates from phosphates in acid media can be enhanced by minimizing free Ca^{2+} in solution and by increasing HPO_4^{2-} in the system. This can be done by (1) decreasing free Ca^{2+} concentration in the system to low values by adding suitable chemical reagents such as sulfuric acid or chelating agents such as oxalic acid, and (2) adding soluble phosphate salts to enhance the depression of the phosphate minerals. Results from experiments with

Figure 11 Adsorption isotherms of oleic acid adsorption on francolite in distilled water and plant water under laboratory and plant conditions. Squares, distilled water in laboratory conditions; open circles, distilled water in plant conditions; filled circles, plant water in plant conditions. natural phosphate ores are in agreement with the theoretical predictions.

Based on the oleic acid solution chemistry, a two-stage conditioning process for the flotation of dolomite from apatite has been proposed. The mixed minerals are first conditioned at pH 10 with oleic acid collector. The system is then reconditioned below pH 4.5 where dolomite is floated. The selectivity of dolomite from apatite is attributed to two factors in this process.

1. High adsorption of oleate on dolomite during the first stage at pH 10, which is maintained after reconditioning at lower pH.
2. Oleate to oleic acid transformation upon reconditioning, reducing its efficiency, and this reduction being more severe for apatite than for dolomite.

In the high pH range, oleate adsorbs on to apatite and calcite through specific interactions, while at low pH, when oleic acid is the major species, the adsorption is through weaker physical interaction. Thus, oleic acid is a poor collector compared to oleate.

Modification of collector adsorption on minerals can be used to control their flotation response. In one study, Alizarin Red S, a dye that stains calcite, was tested as a modifying agent in calcite-apatite system due to its preferential adsorption on these

minerals. Even though Alizarin Red S adsorbs more on apatite than on calcite, it depresses the flotation of apatite using oleate as collector more than that of calcite (Figure 12). In the absence of the dye, both calcite and apatite float with oleate at pH 10.5. When the dye concentration increases to $5 \times 10^{-6} \text{ mol m}^{-3}$, the flotation of calcite is very little affected with a recovery of about 90%, while apatite flotation is depressed to 5–10%. Calcite flotation is only affected at higher concentrations of dye. Alizarin Red S or its derivatives are hence promising reagents for the beneficiation of phosphate with carbonaceous gangues.

Summary

Mineral-solution equilibria, surfactant-solution chemistry, as well as interactions among dissolved species, surfactant and solids, can have a drastic effect on surfactant adsorption and flotation separation of sparingly soluble minerals. Studies on the effects of water chemistry on adsorption of surfactant on phosphate minerals such as apatite and francolite and associated minerals such as calcite and dolomite show that these interactions have marked effects on the reagent adsorption as well as flotation. Surfactant can exist in different forms in solution depending on the solution pH and the surfactant concentration. Minerals can undergo dissolution, with the extent of
